Human Computer Interaction: Concepts, Methodologies, Tools, and Applications

Panayiotis Zaphiris  
*City University of London, UK*

Chee Siang Ang  
*City University of London, UK*
Editor-in-Chief

Mehdi Khosrow-Pour, DBA
Editor-in-Chief
Contemporary Research in Information Science and Technology, Book Series

Associate Editors

Steve Clarke
University of Hull, UK

Murray E. Jennex
San Diego State University, USA

Annie Becker
Florida Institute of Technology USA

Ari-Veikko Anttiloiko
University of Tampere, Finland

Editorial Advisory Board

Sherif Kamel
American University in Cairo, Egypt

In Lee
Western Illinois University, USA

Jerzy Kisielnicki
Warsaw University, Poland

Keng Siau
University of Nebraska-Lincoln, USA

Amar Gupta
Arizona University, USA

Craig van Slyke
University of Central Florida, USA

John Wang
Montclair State University, USA

Vishanth Weerakkody
Brunel University, UK
Additional Research Collections found in the
“Contemporary Research in Information Science and Technology”
Book Series

Data Mining and Warehousing: Concepts, Methodologies, Tools, and Applications
John Wang, Montclair University, USA • 6-volume set • ISBN 978-1-60566-056-1

Electronic Business: Concepts, Methodologies, Tools, and Applications
In Lee, Western Illinois University • 4-volume set • ISBN 978-1-59904-943-4

Electronic Commerce: Concepts, Methodologies, Tools, and Applications
S. Ann Becker, Florida Institute of Technology, USA • 4-volume set • ISBN 978-1-59904-943-4

Electronic Government: Concepts, Methodologies, Tools, and Applications
Ari-Veikko Anttiroiko, University of Tampere, Finland • 6-volume set • ISBN 978-1-59904-947-2

Knowledge Management: Concepts, Methodologies, Tools, and Applications
Murray E. Jennex, San Diego State University, USA • 6-volume set • ISBN 978-1-59904-933-5

Information Communication Technologies: Concepts, Methodologies, Tools, and Applications
Craig Van Slyke, University of Central Florida, USA • 6-volume set • ISBN 978-1-59904-949-6

Intelligent Information Technologies: Concepts, Methodologies, Tools, and Applications
Vijayan Sugumaran, Oakland University, USA • 4-volume set • ISBN 978-1-59904-941-0

Information Security and Ethics: Concepts, Methodologies, Tools, and Applications

Medical Informatics: Concepts, Methodologies, Tools, and Applications
Joseph Tan, Wayne State University, USA • 4-volume set • ISBN 978-1-60566-050-9

Mobile Computing: Concepts, Methodologies, Tools, and Applications
David Taniar, Monash University, Australia • 6-volume set • ISBN 978-1-60566-054-7

Multimedia Technologies: Concepts, Methodologies, Tools, and Applications
Syed Mahbubur Rahman, Minnesota State University, Mankato, USA • 3-volume set • ISBN 978-1-60566-054-7

Virtual Technologies: Concepts, Methodologies, Tools, and Applications
Jerzy Kisielnicki, Warsaw University, Poland • 3-volume set • ISBN 978-1-59904-955-7

List of Contributors

Aaltio, Iiris / Lappeenranta University of Technology, Finland .......................................................... 2030
Abraham, J. R. / University of the West of England, UK ................................................................. 376
Abutarbush, Sameeh M. / University of Prince Edward Island, Canada ........................................ 1656
Adam, Alison / University of Salford, UK ......................................................................................... 2435
Ágerfalk, Pär J. / University of Limerick, Ireland & Örebro University, Sweden ............................ 2341
Ahuja, Manju / Indiana University, USA ......................................................................................... 1736
Ala-Rämi, Katarina / University of Oulu, Finland ........................................................................... 2037
Albert, Sylvie / Laurentian University, Canada .................................................................................. 1915
Aldiri, Khalid / University of Bradford, UK ...................................................................................... 2235
Almeida, Hyggo / Federal University of Campina Grande, Brazil ................................................. 228, 254, 279
Almendros-Jimenez, Jesus M. / Universidad de Almeria, Spain ....................................................... 404
Alpert, Sherman R. / IBM T. J. Watson Research Center, USA ...................................................... 177
Altenhofen, Michael / SAP Research, CEC Karlsruhe, Germany .................................................... 2144
Anagnostopoulos, Christos / University of Athens, Greece ............................................................... 1096
Andersen, Peter Bøgh / University of Aarhus, Denmark ................................................................. 552
Andrade, Stephen C. / Johnson & Wales University, USA ............................................................... 2590
Andrea, Carugati / Catholic University of Lille, France ................................................................. 489
Anke, Juergen / Dresden University of Technology, Germany ......................................................... 168
Ardissono, Liliana / Università de Torino, Italy ................................................................................. 791
Avery Gomez, Elizabeth / New Jersey Institute of Technology, USA ........................................... 1334
Baber, Chris / The University of Birmingham, UK ........................................................................... 80, 1134
Barbosa, Nadia / Federal University of Campina Grande, Brazil .................................................... 279
Beckwith, Laura / Oregon State University, USA ............................................................................. 25
Bellotti, Francesco / University of Genoa, Italy ............................................................................... 1234
Ben Zakour, Amel / FSJEGJ, Tunisia ................................................................................................... 132
Bernsteiner, Reinhard / University for Health Sciences, Medical Informatics and Technology, Austria ................................................................. 1402
Berta, Riccardo / University of Genoa, Italy ..................................................................................... 1234
Bharati, Pratyush / University of Massachusetts, Boston, USA ...................................................... 1956
Bhattacherjee, Anol / University of South Florida, USA ................................................................. 1608
Bias, Randolph G. / The University of Texas at Austin, USA ......................................................... 2404
Bieber, Michael / New Jersey Institute of Technology, USA ............................................................ 1334
Blocher, J. Michael / Northern Arizona University, USA ............................................................... 1547
Blomqvist, Kirsi-Marja / Lappeenranta University of Technology, Finland ..................................... 2181
Bondarouk, Tanya / University of Twente, The Netherlands ............................................................ 2214
Bonk, Curtis J. / Indiana University, USA ......................................................... 1262
Bornhövd, Christof / SAP Research, Research Center Palo Alto, USA .................. 2144
Bourgue, Marie-Luce / Queen Mary University of London, UK .......................... 95
Bowen, Jonathan P. / London South Bank University, UK .............................. 1629
Boyle, Randall J. / University of Utah, USA ..................................................... 1970
Brey, Philip / University of Twente, The Netherlands ..................................... 154
Bruegger, Pascal / University of Fribourg, Switzerland .................................. 1015
Brynskov, Martin / Center for Interactive Spaces, University of Aarhus, Denmark .. 552
Bublitz, Frederico / Federal University of Campina Grande, Brazil ................. 279
Burnett, Gary / University of Nottingham, UK ............................................... 532
Burnett, Margaret / Oregon State University, USA ........................................ 25
Bushey, Robert G. / AT&T Laboratories, USA .............................................. 2404
Bygstad, Bendik / Norwegian School of Information Technology, Norway .......... 2090
Caronia, Letizia / University of Bologna, Italy ............................................. 2655
Castelfranchi, Cristiano / Institute for Cognitive Sciences and Technology, National Research Council of Italy, Italy ...................................................... 2316
Catarci, Tiziana / University of Rome “La Sapienza”, Italy ............................... 872, 928
Chaudhury, Adhijit / Bryant University, USA .............................................. 1956
Chen, Chaomei / Drexel University, USA ..................................................... 1678
Chen, Yen-Jung / National University of Tainan, Taiwan ............................... 1330
Cheuk, Bonnie Wai-yi / Improvement Service for the Scottish Local Government, Scotland ................................................................. 1905
Cigognini, M. E. / University of Florence (IT), Italy ...................................... 961
Clark, Chris / University of Saskatchewan, Canada ........................................ 1656
Cohn, Jonathan / UCLA, USA ................................................................. 2530
Compagna, Luca / SAP Research, France .................................................. 2424
Cox, Anna L. / University College London, UK ........................................... 1154
Crombie, David / DEDICON S.r.l., The Netherlands .................................... 1350
Cyr, Dianne / Simon Fraser University, Canada ........................................... 1761
da Cunha Borelli, Walter / State University of Campinas, Brazil ................. 1037
Dai, Honghua / DePaul University, USA .................................................... 732
Daniel, Ben K. / University of Saskatchewan, Canada ................................... 979
Das, Sajal / University of Texas at Arlington, USA ....................................... 1173
Davenport, Glorianna / The Media Laboratory, USA .................................. 1521
Davis, Donald D. / Old Dominion University, USA ...................................... 2023
de Fátima Queiroz Vieira Turnell, Maria / Universidade Federal de Campina Grande (UFCG), Brazil ................................................................. 2573
De Gloria, Alessandro / University of Genoa, Italy ...................................... 1234
de Queiroz, José Eustáquio Rangel / Universidade Federal de Campina Grande (UFCG), Brazil ................................................................. 2573
de Sousa Ferreira, Danilo / Universidade Federal de Campina Grande (UFCG), Brazil 2573
Deng, Li / Microsoft Research, USA .......................................................... 997
Deng, Liqiong / University of West Georgia, USA ........................................ 850
Diaper, Dan / Middlesex University, UK ..................................................... 70
Dix, Alan / Lancaster University, UK .......................................................... 928
Doyle, D. John / Cleveland Clinic Foundation, USA .................................... 483
Doyle, Linda / University of Dublin, Ireland ................................................................. 2266
Edenius, Mats / Stockholm School of Economics, Sweden ........................................... 2376
El Louadi, Mohamed / University of Tunis, Tunisia ................................................. 123
Elia, Hadzilias / Catholic University of Lille, France ............................................. 489
Erlendson, Benjamin E. / Arizona State University, USA ...................................... 698
Esteves, Jose / Universidade Politecnica de Catalunya, Barcelona, Spain ........ 2132
Evangelou, Christina E. / Research Academic Computer Technology Institute, Greece ... 1044
Falcone, Rino / Institute for Cognitive Sciences and Technology, National Research Council of Italy, Italy ................................................................. 2316
Fan, Haiyan / Texas A&M University, USA ............................................................ 850
Farmer, Rod / The University of Melbourne, Australia ........................................ 899
Ferreira, Glauber / Federal University of Campina Grande, Brazil .................... 228, 279
Filippini-Fantoni, Silvia / The University of Paris I Sorbonne University, France ...... 1629
Fischbach, Kai / University of Cologne, Germany ............................................... 2191
Fitzgerald, Robert / University of Canberra, Australia ........................................ 1459
Fletcher, Gordon / University of Salford, UK ...................................................... 1871
Floridi, Luciano / Università degli Studi di Bari, Italy and Oxford University, UK ...... 2450
Foth, Marcus / Queensland University of Technology, Australia .................. 589
French, Sheila / Manchester Metropolitan University, UK ................................ 2296
Fu, Guohong / The University of Hong Kong, Hong Kong ..................................... 1595
Furtado, Elizabeth / University of Fortaleza, Brazil ........................................... 448
Fuschi, David Luigi / GIUNTI Labs S.r.l., Italy .................................................. 1350
Fussell, Susan R. / Carnegie Mellon University, USA ......................................... 1801
Gabrielli, Silvia / University of Rome “La Sapienza”, Italy ...................................... 928
Gallagher, Kevin / Northern Kentucky University, USA ..................................... 2052
Gefen, David / Drexel University, USA ............................................................. 2644
Gena, Cristina / Università di Torino, Italy .......................................................... 791
George, Joey F. / Florida State University, USA .................................................. 1970
Georgiadis, Christos K. / University of Macedonia, Thessaloniki, Greece ............ 393
Geri, Nitza / The Open University of Israel, Israel ............................................. 2644
Gkotsis, George / Research Academic Computer Technology Institute, Greece .... 1044
Gold, Stuart S. / DeVry University, USA ............................................................. 1864
Goldkuhl, Göran / Linköping University, Sweden & Jönköping International Business School, Sweden .......................................................... 2071, 2341
Greenhill, Anita / The University of Manchester, UK .......................................... 1871, 2259
Greitzer, Frank L. / Pacific Northwest National Laboratory, USA .................. 2693
Griffith, Douglas / General Dynamics Advanced Information Systems, USA ..... 2693
Gruba, Paul / The University of Melbourne, Australia ........................................ 899
Guo, Huaqun / Institute for Infocomm Research and National University of Singapore, Singapore .......................................................... 1087
Gurevych, Iryna / Technische Universität Darmstadt, Germany ......................... 1
Gurram, Rama / SAP Research, USA ................................................................. 102
Hadjithymiades, Stathes / University of Athens, Greece ..................................... 1096
Hall, Jon G. / The Open University, UK ............................................................. 713
Hanrahan, Michael / Bates College, USA ............................................................ 1251
Heinemann, Andreas / Technical University of Darmstadt, Germany .............. 333
Henttonen, Kaisa / Lappeenranta University of Technology, Finland .............................................. 2181
Her, One-Soon / National Chengchi University, Taiwan ................................................................. 2499
Herdin, Thomas / University of Salzburg, Austria ........................................................................ 1055
Herring, Susan C. / Indiana University, USA .................................................................................. 1736
Hirsbrunner, Béat / University of Fribourg, Switzerland ............................................................... 1015
Hobbs, Dave / University of Bradford, UK .................................................................................... 2235
Hofkirchner, Wolfgang / University of Salzburg, Austria .............................................................. 1055
Hohmann, Claus / Bergische Universität Wuppertal, Germany ....................................................... 2462
Hornik, Steven / University of Central Florida, USA .................................................................. 1885
Horowitz, Ellis / University of Southern California, USA .............................................................. 659
Hsu, HY Sonya / Southern Illinois University, USA ....................................................................... 1649
Hsu, Jeffrey / Fairleigh Dickinson University, USA ......................................................................... 1308
Hsu, Shang Hwa / National Chiao Tung University, Taiwan ......................................................... 516
Huang, Haiyan / The Pennsylvania State University, USA ............................................................ 1753
Huang, Rui / University of Texas at Arlington, USA .................................................................... 1173
Hubona, Geoffrey S. / Georgia State University, USA ................................................................. 2473
Huffaker, David A. / Northwestern University, USA ..................................................................... 1484
Hürt, Wolfgang / Albert-Ludwigs-Universität Freiburg, Germany .............................................. 1436
Hwang, Gwo-Jen / National University of Tainan, Taiwan ............................................................. 1330
Iribarne, Luis / Universidad de Almeria, Spain ............................................................................. 404
Isomäki, Hannakaisa / University of Lapland, Finland ................................................................. 605
James, Frankie / SAP Research, USA ............................................................................................ 102
Jaspers, M.W.M. / University of Amsterdam, The Netherlands .................................................. 622
Jefsioutine, Marie / University of Central England - Birmingham, UK ....................................... 432
Jin, Dal Yong / Simon Fraser University, Canada ........................................................................... 1200
José Luzón, Maria / University of Zaragoza, Spain ....................................................................... 1291
Julien, Christine / The University of Texas at Austin, USA ............................................................. 2708
Kabadayi, Sanem / The University of Texas at Austin, USA .......................................................... 2708
Kacmar, Charles J. / The University of Alabama, USA ................................................................. 1970
Karali, Izambo / University of Athens, Greece ............................................................................. 1096
Karousos, Nikos / National Hellenic Research Foundation, Greece ........................................... 1044
Khattab, Ishragna / Brunel University, UK ..................................................................................... 1569
Kidd, Terry T. / University of Texas School of Public Health, USA ............................................. 1468
Kimani, Stephen / Jomo Kenyatta University of Agriculture and Technology, Kenya, & University of Rome “La Sapienza”, Italy ......................................................... 872, 928
Kirakowski, Jurek / University College Cork, Ireland ................................................................. 361
Klassen, Myungsook / California Lutheran University, USA ......................................................... 1729
Kleinschmidt, João Henrique / State University of Campinas, Brazil ......................................... 1037
Klinker, Gudrun / Technische Universität München, Germany ...................................................... 629
Klobas, Jane / Bocconi University, Italy & University of Western Australia, Australia ................ 1283
Knight, James / The University of Birmingham, UK ...................................................................... 1134
Knight, John / University of Central England - Birmingham, UK ............................................. 432
Knott, Benjamin A. / U.S. Air Force Research Laboratory, USA .................................................. 2404
Kolomvatsos, Kostas / National & Kapodistrian University of Athens, Greece ......................... 1503
Kortum, Kortum / Rice University, USA ....................................................................................... 2404

Contents
by Volume

Volume I.

Section I. Fundamental Concepts and Theories

This section serves as the foundation for this exhaustive reference tool by addressing crucial theories essential to the understanding of human-computer interaction. Chapters found within these pages provide an excellent framework in which to position human-computer interaction within the field of information science and technology. Individual contributions provide overviews of ubiquitous computing, cognitive informatics, and sociotechnical theory, while also exploring critical stumbling blocks of this field. Within this introductory section, the reader can learn and choose from a compendium of expert research on the elemental theories underscoring the research and application of human-computer interaction.

Chapter 1.1 Introduction to Ubiquitous Computing /
Max Mühlhäuser, Technische Universität Darmstadt, Germany;
and Iryna Gurevych, Technische Universität Darmstadt, Germany ............................................................... 1

Chapter 1.2 Ubiquitous Computing and the Concept of Context /
Antti Oulasvirta, Helsinki Institute for Information Technology, Finland;
and Antti Salovaara, Helsinki Institute for Information Technology, Finland ................................................. 20

Chapter 1.3 Gender and End-User Computing / Laura Beckwith, Oregon State University, USA;
Margaret Burnett, Oregon State University, USA;
and Shraddha Sorte, Oregon State University, USA ......................................................................................... 25

Chapter 1.4 The Theoretical Framework of Cognitive Informatics /
Yingxu Wang, University of Calgary, Canada ..................................................................................................... 33

Chapter 1.5 Human Factors in Public Information Systems /
Karl W. Sandberg, Mid Sweden University, Sweden;
and Pan Yan, Luleå University of Technology, Sweden ...................................................................................... 60
Chapter 1.6 Task Analysis at the Heart of Human-Computer Interaction / 
Dan Diaper, Middlesex University, UK ................................................................. 70

Chapter 1.7 Evaluating Mobile Human-Computer Interaction / 
Chris Baber, The University of Birmingham, UK .................................................. 80

Chapter 1.8 An Overview of Multimodal Interaction Techniques and Applications / 
Marie-Luce Bourguet, Queen Mary University of London, UK ................................. 95

Chapter 1.9 Multimodal and Federated Interaction / Frankie James, SAP Research, USA; and Rama Gurram, SAP Research, USA ........................................................................... 102

Chapter 1.10 The Arab World, Culture and Information Technology / 
Mohamed El Louadi, University of Tunis, Tunisia .................................................... 123

Chapter 1.11 Information Technology Acceptance across Cultures / 
Amel Ben Zakour, FSJEGJ, Tunisia ........................................................................... 132

Chapter 1.12 Is Information Ethics Culture-Relative? / 
Philip Brey, University of Twente, The Netherlands ............................................... 154

Chapter 1.13 Personalization Techniques and Their Application / 
Juergen Anke, Dresden University of Technology, Germany; and David Sundaram, University of Auckland, New Zealand ................................................................. 168

Chapter 1.14 User-Centered Evaluation of Personalized Web Sites: What’s Unique? / 
Sherman R. Alpert, IBM T. J. Watson Research Center, USA; and John G. Vergo, IBM T. J. Watson Research Center, USA ........................................................................... 177

Chapter 1.15 The Usability Engineering Behind User-Centered Processes 
for Web Site Development Lifecycles / Theresa A. O’Connell, Humans & Computers, Inc., USA; and Elizabeth D. Murphy, U.S. Census Bureau, USA ......................................................... 192

Chapter 1.16 Personalization Systems and Their Deployment as Web Site Interface 
Design Decisions / Nanda Kumar, Baruch College, The City University of New York, USA .............. 212

Chapter 1.17 Communication + Dynamic Interface = Better User Experience / 
Simon Polovina, Sheffield Hallam University, UK; and Will Pearson, Sheffield Hallam 
University, UK ........................................................................................................ 220

Chapter 1.18 Pervasive Computing: What Is It Anyway? / 
Emerson Loureiro, Federal University of Campina Grande, Brazil; 
Glauber Ferreira, Federal University of Campina Grande, Brazil; 
Hyggo Almeida, Federal University of Campina Grande, Brazil; and Angelo Perkusich, Federal University of Campina Grande, Brazil ......................................................... 228
Chapter 1.19 Pervasive and Grid Computing Merging / Loreno Oliveira, Federal University of Campina Grande, Brazil; Emerson Loureiro, Federal University of Campina Grande, Brazil; Higgo Almeida, Federal University of Campina Grande, Brazil; and Angelo Perkusich, Federal University of Campina Grande, Brazil ................................................................. 254

Chapter 1.20 Leveraging Pervasive and Ubiquitous Service Computing / Zhijun Zhang, University of Phoenix, USA ......................................................................................... 262

Chapter 1.21 Service Provision for Pervasive Computing Environments / Emerson Loureiro, Federal University of Campina Grande, Brazil; Frederico Bublitz, Federal University of Campina Grande, Brazil; Loreno Oliveira, Federal University of Campina Grande, Brazil; Nadia Barbosa, Federal University of Campina Grande, Brazil; Angelo Perkusich, Federal University of Campina Grande, Brazil; Higgo Almeida, Federal University of Campina Grande, Brazil; and Glauber Ferreira, Federal University of Campina Grande, Brazil ................................................................. 279

Chapter 1.23 Computer-Mediated Communication Research / J. D. Wallace, Lubbock Christian University, USA ................................................................................................. 299

Chapter 1.24 Computer-Mediated Communication in Virtual Learning Communities / Lisa Link, Flensburg University of Applied Sciences, Germany; and Daniela Wagner, University of Hildesheim, Germany ................................................................................... 316

Chapter 1.25 Human-Computer Interaction and Security / Kai Richter, Computer Graphics Centre (ZGDV), Germany; and Volker Roth, OGM Laboratory LLC, USA ........................................................................ 323

Chapter 1.26 Security for Ubiquitous Computing / Tobias Straub, Fraunhofer Institute for Secure Information Technology, Germany; and Andreas Heinemann, Technical University of Darmstadt, Germany ........................................................................ 333

Section II. Development and Design Methodologies

This section provides in-depth coverage of conceptual architectures, frameworks and methodologies related to the design and implementation of interfaces and technologies that promote successful human-computer interaction. Throughout these contributions, research fundamentals in the discipline are presented and discussed. From broad examinations to specific discussions on particular frameworks and infrastructures, the research found within this section spans the discipline while also offering detailed, specific discussions. Basic designs, as well as abstract developments, are explained within these chapters, and frameworks for designing and personalizing interfaces for medical equipment, televisions, and automobiles are discussed.
Chapter 2.1 Measuring the Human Element in Complex Technologies / Niamh McNamara, University College Cork, Ireland; and Jurek Kirakowski, University College Cork, Ireland ......................................................... 361

Chapter 2.2 Human-Centric Evolutionary Systems in Design and Decision-Making / I. C. Parmee, University of the West of England, UK; J. R. Abraham, University of the West of England, UK; and A. Machwe, University of the West of England, UK ............................................................................. 376

Chapter 2.3 Adaptation and Personalization of User Interface and Content / Christos K. Georgiadis, University of Macedonia, Thessaloniki, Greece ................................................................. 393

Chapter 2.4 User Interaction and Interface Design with UML / Jesus M. Almendros-Jimenez, Universidad de Almeria, Spain; and Luis Iribarne, Universidad de Almeria, Spain ........................................................................... 404

Chapter 2.5 Design Methods for Experience Design / Marie Jefsioutine, University of Central England–Birmingham, UK; and John Knight, University of Central England–Birmingham, UK ............................................................ 432

Chapter 2.6 Integrating Usability, Semiotic, and Software Engineering into a Method for Evaluating User Interfaces / Kenia Sousa, University of Fortaleza, Brazil; Albert Schilling, University of Fortaleza, Brazil; and Elizabeth Furtado, University of Fortaleza, Brazil ........................................................................... 448

Chapter 2.7 Guidance in the Interface: Effects of Externalizing Information During Problem Solving / Christof van Nimwegen, Utrecht University, The Netherlands; Hermina Tabachneck-Schijf, Utrecht University, The Netherlands; and Herre van Oostendorp, Utrecht University, The Netherlands ....................................................................... 465

Chapter 2.8 Ergonomic User Interface Design in Computerized Medical Equipment / D. John Doyle, Cleveland Clinic Foundation, USA ............................................................................................. 483

Chapter 2.9 Development Of E-Government Services For Cultural Heritage: Examining the Key Dimensions / Carugati Andrea, Catholic University of Lille, France; and Hadziliyas Elias, Catholic University of Lille, France .............................................................................................. 489

Chapter 2.10 An Activity-Oriented Approach to Designing a User Interface for Digital Television / Shang Hwa Hsu, National Chiao Tung University, Taiwan; Ming-Hui Weng, National Chiao Tung University, Taiwan; and Cha-Hoang Lee, National Chiao Tung University, Taiwan .............................................................................. 516

Chapter 2.11 Designing and Evaluating In-Car User-Interfaces / Gary Burnett, University of Nottingham, UK ......................................................................................................................... 532
Chapter 2.12 The Semiotics of Smart Appliances and Pervasive Computing / 
Peter Bøgh Andersen, University of Aarhus, Denmark; 
and Martin Brynskov, Center for Interactive Spaces, University of Aarhus, Denmark .................. 552

Chapter 2.13 Analyzing the Factors Influencing the Successful Design 
and Uptake of Interactive Systems to Support Social Networks in Urban Neighborhoods / 
Marcus Foth, Queensland University of Technology, Australia ......................................................... 589

Chapter 2.14 Different Levels of Information Systems Designers’ 
Forms of Thought and Potential for Human-Centered Design / 
Hannakaisa Isomäki, University of Lapland, Finland ........................................................................ 605

Chapter 2.15 The Think Aloud Method and User Interface Design / 
M.W.M. Jaspers, University of Amsterdam, The Netherlands ............................................................ 622

Chapter 2.16 Lessons Learned in Designing Ubiquitous Augmented Reality User Interfaces / 
Christian Sandor, Technische Universität München, Germany; 
and Gudrun Klinker, Technische Universität München, Germany ...................................................... 629

Chapter 2.17 Social Network Structures in Open Source Software Development Teams / 
Yuan Long, Colorado State University-Pueblo, USA; 
and Keng Siau, University of Nebraska-Lincoln, USA ....................................................................... 645

Volume II.

Chapter 2.18 A Graphical User Interface (GUI) Testing Methodology / 
Zafar Singhera, ZAF Consulting, USA; Ellis Horowitz, University of Southern California, USA; 
and Abad Shah, R & D Center of Computer Science, Pakistan ............................................................ 659

Chapter 2.19 Socio-Cognitive Engineering / 
Mike Sharples, University of Nottingham, Jubilee Campus, UK .......................................................... 677

Chapter 2.20 On the Cognitive Processes of Human Perception 
with Emotions, Motivations, and Attitudes / Yingxu Wang, University of Calgary, Canada .............. 685

Chapter 2.21 Sociotechnical System Design for Learning: Bridging 
the Digital Divide with CompILE / Benjamin E. Erlandson, Arizona State University, USA ............ 698

Chapter 2.22 Problem Frames for Sociotechnical Systems / Jon G. Hall, The Open University, UK; 
and Lucia Rapanotti, The Open University, UK ...................................................................................... 713

Chapter 2.23 Integrating Semantic Knowledge with Web Usage Mining for Personalization / 
Honghua Dai, DePaul University, USA; and Bamshad Mobasher, DePaul University, USA ............. 732
Chapter 2.24 Modeling Variant User Interfaces for Web-Based Software Product Lines / Suet Chun Lee, BUSINEX, Inc., USA ................................................................. 760

Chapter 2.25 A User-Centered Approach to the Retrieval of Information in an Adaptive Web Site / Cristina Gena, Università di Torino, Italy; and Liliana Ardisono, Università di Torino, Italy .... 791

Chapter 2.26 Auto-Personalization Web Pages / Jon T. S. Quah, Nanyang Technological University, Singapore; Winnie C. H. Leow, Singapore Polytechnic, Singapore; K. L. Yong, Nanyang Technological University, Singapore .................................................. 807

Chapter 2.27 A Qualitative Study in User’s Information-Seeking Behaviors on Web Sites: A User-Centered Approach to Web Site Development / Napawan Sawasdichai, King Mongkut’s Institute of Technology, Thailand ............................................. 816

Chapter 2.28 Developing and Validating a Measure of Web Personalization Strategy / Haiyan Fan, Texas A&M University, USA; and Liqiong Deng, University of West Georgia, USA... 850

Chapter 2.29 User Interface Formalization in Visual Data Mining / Tiziana Catarci, University of Rome “La Sapienza”, Italy; Stephen Kimani, University of Rome “La Sapienza”, Italy; and Stefano Lodi, University of Bologna, Italy .......................................................... 872

Chapter 2.30 Understanding the Nature of Task Analysis in Web Design / Rod Farmer, The University of Melbourne, Australia; and Paul Gruba, The University of Melbourne, Australia ......................................................... 899

Chapter 2.31 Designing for Tasks in Ubiquitous Computing: Challenges and Considerations / Stephen Kimani, Jomo Kenyatta University of Agriculture and Technology, Kenya; Silvia Gabrielli, University of Rome “La Sapienza”, Italy; Tiziana Catarci, University of Rome “La Sapienza”, Italy; and Alan Dix, Lancaster University, UK ........................................................................ 928

Chapter 2.32 Task Ontology-Based Human-Computer Interaction / Kazuhisa Seta, Osaka Prefecture University, Japan ................................................................. 950

Chapter 2.33 Social Networking Theories and Tools to Support Connectivist Learning Activities / M. C. Pettenati, University of Florence (IT), Italy; and M. E. Cigognini, University of Florence (IT), Italy ............................................................... 961

Chapter 2.34 User-Centered Design Principles for Online Learning Communities: A Sociotechnical Approach for the Design of a Distributed Community of Practice / Ben K. Daniel, University of Saskatchewan, Canada; David O’Brien, University of Saskatchewan, Canada; and Asit Sarkar, University of Saskatchewan, Canada ........................................................................ 979
Chapter 2.35 Content Personalization for Mobile Interfaces /  
Spiridoula Koukia, University of Patras, Greece;  
Maria Rigou, University of Patras, Greece & Research Academic Computer Technology Institute, Greece; and Spiros Sirmakessis, Technological Institution of Messolongi, Greece  
Research Academic Computer Technology Institute, Greece

Chapter 2.36 Speech-Centric Multimodal User Interface Design in Mobile Technology /  
Dong Yu, Microsoft Research, USA; and Li Deng, Microsoft Research, USA

Chapter 2.37 Kinetic User Interfaces: Physical Embodied Interaction with Mobile Ubiquitous Computing Systems /  
Vincenzo Pallotta, University of Fribourg, Switzerland;  
Pascal Bruegger, University of Fribourg, Switzerland; and Béat Hirsbrunner, University of Fribourg, Switzerland

Section III. Tools and Technologies

This section presents extensive coverage of specific tools and technologies that humans interact with and react to in their daily lives. These chapters provide an in-depth analysis of devices and tools such as portable music players, mobile phones, and even blogs. Within these rigorously researched chapters, readers are presented with countless examples of the technologies that support and encourage societal development and their resulting impact.

Chapter 3.1 Enabling Technologies for Pervasive Computing /  
João Henrique Kleinschmidt, State University of Campinas, Brazil; and Walter da Cunha Borelli, State University of Campinas, Brazil

Chapter 3.2 Augmenting Collaboration with Personalization Services /  
Christina E. Evangelou, Research Academic Computer Technology Institute, Greece;  
Manolis Tzagarakis, Research Academic Computer Technology Institute, Greece;  
Nikos Karousos, Research Academic Computer Technology Institute, Greece;  
George Gkotsis, Research Academic Computer Technology Institute, Greece; and Dora Nousia, Research Academic Computer Technology Institute, Greece

Chapter 3.3 Culture and Technology: A Mutual-Shaping Approach /  
Thomas Herdin, University of Salzburg, Austria;  
Wolfgang Hofkirchner, University of Salzburg, Austria; and Ursula Maier-Rabler, University of Salzburg, Austria

Chapter 3.4 Importance of Interface Agent Characteristics from End-User Perspective /  
Alexander Serenko, Lakehead University, Canada

Chapter 3.5 Web Mining for Public E-Services Personalization /  
Penelope Markellou, University of Patras, Greece; Angeliki Panayiotaki, University of Patras, Greece; and Athanasios Tsakalidis, University of Patras, Greece
Chapter 3.16 Plagiarism, Instruction, and Blogs / Michael Hanrahan, Bates College, USA .......... 1251

Chapter 3.17 Twin Wiki Wonders? Wikipedia and Wikibooks as Powerful Tools for Online Collaborative Writing / Meng-Fen Grace Lin, University of Houston, USA; Curtis J. Bonk, Indiana University, USA; and Suthiporn Sajjanaraj, Indiana University, USA .... 1262

Chapter 3.18 Wikis as Tools for Collaboration / Jane Klobas, Bocconi University, Italy & University of Western Australia, Australia ................................................................. 1283

Chapter 3.19 Academic Weblogs as Tools for E-Collaboration Among Researchers / María José Luzón, University of Zaragoza, Spain ................................................................. 1291

Chapter 3.20 Assessing Weblogs as Education Portals / Ian Weber, Texas A&M University, USA ......................................................................................................................... 1298

Chapter 3.21 Innovative Technologies for Education and Learning: Education and Knowledge-Oriented Applications of Blogs, Wikis, Podcasts, and More / Jeffrey Hsu, Fairleigh Dickinson University, USA ......................................................................................... 1308

Chapter 3.22 Ubiquitous Computing Technologies in Education / Gwo-Jen Hwang, National University of Tainan, Taiwan; Ting-Ting Wu, National University of Tainan, Taiwan; and Yen-Jung Chen, National University of Tainan, Taiwan ........................................ 1330

Chapter 3.23 Utilizing Web Tools for Computer-Mediated Communication to Enhance Team-Based Learning / Elizabeth Avery Gomez, New Jersey Institute of Technology, USA; Dezhi Wu, Southern Utah University, USA; Katia Passerini, New Jersey Institute of Technology, USA; and Michael Bieber, New Jersey Institute of Technology, USA ......................................................................................... 1334

Volume III.

Chapter 3.24 How Technology Can Support Culture and Learning / David Luigi Fuschi, GIUNTI Labs S.r.l., Italy; Bee Ong, University of Leeds, UK; and David Crombie, DEDICON S.r.l., The Netherlands ......................................................... 1350

Chapter 3.25 Tangible User Interfaces as Mediating Tools within Adaptive Educational Environments / Daria Loi, RMIT University, Australia ......................................................................................... 1388

Chapter 3.26 Facilitating E-Learning with Social Software: Attitudes and Usage from the Student’s Point of View / Reinhard Bernsteiner, University for Health Sciences, Medical Informatics and Technology, Austria; Herwig Ostermann, University for Health Sciences, Medical Informatics and Technology, Austria; and Roland Staudinger, University for Health Sciences, Medical Informatics and Technology, Austria ......................................................................................... 1402
Section IV. Utilization and Application

This section introduces and discusses the ways in which particular technologies have impacted humanity and proposes new ways in which IT-related innovations can be implemented within organizations and in society as a whole. These particular selections highlight, among other topics, ubiquitous computing applications in an educational setting and computer-mediated communication. Contributions included in this section provide excellent coverage of today’s world and insight into how our interaction with technology impacts the fabric of our present-day global village.

Chapter 4.1 Human Computer Interaction and the Best Mix of Face-to-Face and E-Interactions in Educational Settings / Bolanle A. Olaniran, Texas Tech University, USA ................................. 1423

Chapter 4.2 Human Computer Interaction for Computer-Based Classroom Teaching / Wolfgang Hürst, Albert-Ludwigs-Universität Freiburg, Germany; and Khaireel A. Mohamed, Albert-Ludwigs-Universität Freiburg, Germany ........................................ 1436

Chapter 4.3 Wikis as an Exemplary Model of Open Source Learning / Robert Fitzgerald, University of Canberra, Australia ........................................................................................................ 1459

Chapter 4.4 Re-Examining the Socioeconomic Factors Affecting Technology Use in Mathematics Classroom Practices / Emiel Owens, Texas Southern University, USA; Holim Song, Texas Southern University, USA; and Terry T. Kidd, University of Texas School of Public Health, USA .................................................................................. 1468

Chapter 4.5 Let Them Blog: Using Weblogs to Advance Literacy in the K-12 Classroom / David A. Huffaker, Northwestern University, USA .................................................................................. 1484

Chapter 4.6 Ubiquitous Computing Applications in Education / Kostas Kolomvatsos, National & Kapodistrian University of Athens, Greece .............................................................. 1503

Chapter 4.7 Unraveling the Taste Fabric of Social Networks / Hugo Liu, The Media Laboratory, USA; Pattie Maes, The Media Laboratory, USA; and Glorianna Davenport, The Media Laboratory, USA .................................................................................. 1521

Chapter 4.8 Computer-Mediated Communication: Enhancing Online Group Interactions / J. Michael Blocher, Northern Arizona University, USA .............................................................................. 1547

Chapter 4.9 Mobile Phone Use Across Cultures: A Comparison Between the United Kingdom and Sudan / Ishraga Khattab, Brunel University, UK; and Steve Love, Brunel University, UK .................................................................................. 1569

Chapter 4.10 Gender and Computing at University in the UK / Ruth Woodfield, University of Sussex, UK .......................................................................................................................... 1583

Chapter 4.11 Gender and Information Technology in Rural Bangladesh / Lutfor Rahman, Association for Advancement of Information Technology (AAIT), Bangladesh; and Nusrat Rahman, University of Dhak and Association for Advancement of Information Technology (AAIT), Bangladesh ........................................................................ 1591
Chapter 4.12 Chinese POS Disambiguation and Unknown Word Guessing with Lexicalized HMMs / Guohong Fu, The University of Hong Kong, Hong Kong; and Kang-Kwong Luke, The University of Hong Kong, Hong Kong ................................................................. 1595

Chapter 4.13 IT Implementation in a Developing Country Municipality: A Sociocognitive Analysis / Clive Sanford, Aalborg University, Denmark; and Anol Bhattacharjee, University of South Florida, USA ................................................................. 1608

Chapter 4.14 Personalization Issues for Science Museum Web Sites and E-Learning / Silvia Filippini-Fantoni, The University of Paris I Sorbonne University, France; Jonathan P. Bowen, London South Bank University, UK; Teresa Numerico, London South Bank University, UK ................................................................. 1629

Chapter 4.15 Personalization and Customer Satisfaction in Mobile Commerce / HY Sonya Hsu, Southern Illinois University, USA; and Songpol Kulviwat, Hofstra University, USA ................................................................. 1649

Chapter 4.16 Integrating Human Computer Interaction in Veterinary Medicine Curricula / Gale Parchoma, University of Saskatchewan, Canada; Susan M. Taylor, University of Saskatchewan, Canada; Jonathan M. Naylor, Ross University School of Veterinary Medicine, West Indies; Sameeh M. Abutarbush, University of Prince Edward Island, Canada; Katharina L. Lohmann, University of Saskatchewan, Canada; Kathy Schwarz, University of Saskatchewan, Canada; Cheryl Waldner, University of Saskatchewan, Canada; Sharon Porterfield, University of Saskatchewan, Canada; Cindy L. Shmon, University of Saskatchewan, Canada; Lydden Polley, University of Saskatchewan, Canada; Chris Clark, University of Saskatchewan Canada ................................................................. 1656

Chapter 4.17 Portals in Consumer Search Behavior and Product Customization / Ian Michael, Zayed University, UAE ................................................................. 1673

Chapter 4.18 Human Factors in the Development of Trend Detection and Tracking Techniques / Chaomei Chen, Drexel University, USA; Kaushal Toprani, Drexel University, USA; and Natasha Lobo, Drexel University, USA ................................................................. 1678

Chapter 4.19 The Internet, Health Information, and Managing Health: An Examination of Boomers and Seniors / Christopher G. Reddick, The University of Texas at San Antonio, USA ................................................................. 1687

Chapter 4.20 The Online Effect: Transitioning from the Legacy Help Desk to the Online Task Management System / Kym Mawson-Lee, University of New South Wales, Australia ................................. 1707

Section V. Organizational and Social Implications

This section includes a wide range of research pertaining to the social and organizational impact of human-computer interaction around the world. Chapters introducing this section analyze gender diff-
ferences in the adoption and reaction to IT, while later contributions offer an extensive analysis of differing social and cultural dimensions of technology adoption. The inquiries and methods presented in this section offer insight into the implications of human-computer interaction at both a personal and organizational level, while also emphasizing potential areas of study within the discipline.

Chapter 5.1 Gender, Race, Social Class and Information Technology / Myungsook Klassen, California Lutheran University, USA; and Russell Stockard, California Lutheran University, USA................................................................. 1729

Chapter 5.2 Gender and the Culture of Computing in Applied IT Education / Susan C. Herring, Indiana University, USA; Christine Ogan, Indiana University, USA; Manju Ahuja, Indiana University, USA; and Jean C. Robinson, Indiana University, USA.......... 1736

Chapter 5.3 Gender Equalization in Computer-Mediated Communication / Rosalie J. Ocker, The Pennsylvania State University, USA ................................................................. 1745

Chapter 5.4 The Cross-Cultural Dimension of Gender and Information Technology / Haiyan Huang, The Pennsylvania State University, USA........................................................................ 1753

Chapter 5.5 Enhancing E-Collaboration Through Culturally Appropriate User Interfaces / Dianne Cyr, Simon Fraser University, Canada ...................................................... 1761

Chapter 5.6 Cultural Barriers of Human-Computer Interaction / Deborah Sater Carstens, Florida Institute of Technology, USA ........................................................................ 1769

Chapter 5.7 Technology and Culture: Indian Experiences / Ramesh C. Sharma, Indira Gandhi National Open University, India; and Sanjaya Mishra, Indira Gandhi National Open University, India...................................................... 1777

Chapter 5.8 Intercultural Computer-Mediated Communication Between Chinese and U.S. College Students / Yun Xia, Rider University, USA ............................................................. 1786

Chapter 5.9 Global Culture and Computer Mediated Communication / Susan R. Fussell, Carnegie Mellon University, USA; Qiping Zhang, Long Island University, USA; and Leslie D. Setlock, Carnegie Mellon University, USA................................................................. 1801

Chapter 5.10 Linguistics of Computer-Mediated Communication: Approaching the Metaphor / Rosanna Tarsiero, Gionnethics, Italy .............................................................. 1817

Chapter 5.11 Impression Formation in Computer-Mediated Communication and Making a Good (Virtual) Impression / Jamie S. Switzer, Colorado State University, USA .... 1837

Chapter 5.12 Group Decision Making in Computer-Mediated Communication as Networked Communication: Understanding the Technology and Implications / Bolanle A. Olaniran, Texas Tech University, USA ........................................................................ 1849

Chapter 5.13 Effects of Computer-Mediated Communication / Stuart S. Gold, DeVry University, USA ........................................................................ 1864
Chapter 5.14 Exploring “Events” as an Information Systems Research Methodology / Anita Greenhill, The University of Manchester, UK; and Gordon Fletcher, University of Salford, UK ................................................................. 1871

Chapter 5.15 Culture’s Impact on Technology Mediated Learning: The Role of Horizontal and Vertical Individualism and Collectivism / Steven Hornik, University of Central Florida, USA; and Anna Tupchiy, University of Central Florida, USA ........................................................................................................ 1885

Chapter 5.16 Using Social Networking Analysis to Facilitate Knowledge Sharing in the British Council / Bonnie Wai-yi Cheuk, Improvement Service for the Scottish Local Government, Scotland ........................................................................................................ 1905

Chapter 5.17 Collaboration Challenges in Community Telecommunication Networks / Sylvie Albert, Laurentian University, Canada; Rolland LeBrasseur, Laurentian University, Canada ........................................................................................................ 1915

Chapter 5.18 Planning and Managing the Human Factors for the Adoption and Diffusion of Object-Oriented Software Development Processes / Magdy K. Serour, University of Technology, Sydney, Australia ........................................................................................................ 1937

Chapter 5.19 Product Customization on the Web: An Empirical Study of Factors Impacting Choiceboard User Satisfaction / Pratyush Bharati, University of Massachusetts, Boston, USA; and Abhijit Chaudhury, Bryant University, USA ........................................................................................................ 1956

Chapter 5.20 Distributed Deception: An Investigation of the Effectiveness of Deceptive Communication in a Computer-Mediated Environment / Randall J. Boyle, University of Utah, USA; Charles J. Kacmar, The University of Alabama, USA; and Joey F. George, Florida State University, USA ........................................................................................................ 1970

Chapter 5.21 Extrinsic Plus Intrinsic Human Factors Influencing the Web Usage / Manuel Jesús Sánchez-Franco, University of Seville, Spain ........................................................................................................ 1995

Section VI. Managerial Impact

This section presents contemporary coverage of the managerial implications of human-computer interaction. Particular contributions address virtual networking, knowledge blogs in company environments, and ambient business. The managerial research provided in this section allows executives, practitioners, and researchers to gain a better sense of the relationship between of business, technology, and individuals.

Chapter 6.1 Social Impact of Virtual Networking / Hakikur Rahman, SDNP Bangladesh, Bangladesh ........................................................................................................ 2014

Chapter 6.2 Gender and Telework in Information Technology / Paula F. Saddler, Association of Certified Fraud Examiners, USA; Donald D. Davis, Old Dominion University, USA;
Chapter 6.3 Managerial Careers, Gender, and Information Technology Field / Iiris Aaltio, Lappeenranta University of Technology, Finland ................................................................. 2030

Chapter 6.4 Social Networking and Knowledge Transfer in Collaborative Product Development / Katariina Ala-Rämi, University of Oulu, Finland .............................................................................. 2037

Chapter 6.5 Reframing Information System Design as Learning Across Communities of Practice / Kevin Gallagher, Northern Kentucky University, USA; and Robert M. Mason, University of Washington, USA ........................................................................ 2052

Chapter 6.6 Grounding Business Interaction Models: Socio-Instrumental Pragmatism as a Theoretical Foundation / Göran Goldkuhl, Linköping University & Jönköping International Business School, Sweden; and Mikael Lind, University College of Borås, Sweden, & Linköping University, Sweden ................................................................. 2071

Chapter 6.7 Managing Socio-Technical Integration in Iterative Information System Development Projects / Bendik Bygstad, Norwegian School of Information Technology, Norway. 2090

Chapter 6.8 Human Factors for Networked and Virtual Organizations / Vincent E. Lasnik, Independent Knowledge Architect, USA .................................................................................. 2106

Chapter 6.9 Trust in Computer-Mediated Communications: Implications for Individuals and Organizations / Susan K. Lippert, Drexel University, USA ..................................................................... 2118

Chapter 6.10 Understanding an ERP System Implementation in a Higher Education Institution: A Grounded Theory Approach / Jose Esteves, Universitat Politècnica de Catalunya, Barcelona, Spain; and Joan Pastor, Universitat Internacional de Catalunya, Barcelona, Spain ........................................................................................................ 2132

Chapter 6.11 Ontologies for Scalable Services-Based Ubiquitous Computing / Daniel Oberle, SAP Research, CEC Karlsruhe, Germany; Christof Bornhövd, SAP Research, Research Center Palo Alto, USA; and Michael Altenhofen, SAP Research, CEC Karlsruhe, Germany .................................................................................. 2144

Chapter 6.12 Web Personalization for E-Marketing Intelligence / Penelope Markellou, University of Patras, Greece & Research Academic Computer Technology Institute, Greece; Maria Rigou, University of Patras, Greece & Research Academic Computer Technology Institute, Greece; and Spiros Sirmakessis, Technological Educational Institution of Messolongi, Greece & Research Academic Computer Technology Institute, Greece ........................................................................ 2164

Chapter 6.13 Knowledge Blogs in Firm Internal Use / Miia Kosonen, Lappeenranta University of Technology, Finland;
Kaisa Henttonen, Lappeenranta University of Technology, Finland; and Kirsimarja Blomqvist, Lappeenranta University of Technology, Finland ........................................ 2181

Chapter 6.14 Towards Ambient Business: Enabling Open Innovation in a World of Ubiquitous Computing / Christian Schmitt, University of Cologne, Germany; Detlef Schoder, University of Cologne, Germany; Kai Fischbach, University of Cologne, Germany; and Steffen Muhle, University of Cologne, Germany ................................................................. 2191

Chapter 6.15 Successes and Failures of SAP Implementation: A Learning Perspective / Tanya Bondarouk, University of Twente, The Netherlands; and Maarten van Riemsdijk, University of Twente, The Netherlands ................................................................................................................. 2214

Chapter 6.16 The Human Face of E-Business: Engendering Consumer Initial Trust Through the Use of Images of Sales Personnel on E-Commerce Web Sites / Khalid Aldiri, University of Bradford, UK; Dave Hobbs, University of Bradford, UK; Rami Qahwaji, University of Bradford, UK ................................................................................................................. 2235

Section VII. Critical Issues

This section addresses conceptual and theoretical issues related to the field of human-computer interaction. Within these chapters, the reader is presented with analysis of the most current and relevant conceptual inquires within this growing field of study. Particular chapters address particular algorithms for web personalization, sociotechnical change, and security for ubiquitous computing systems. Overall, contributions within this section ask unique, often theoretical questions related to the study of human-computer interaction and, more often than not, conclude that solutions are both numerous and contradictory.

Chapter 7.1 Gender, Place, and Information Technology / Anita Greenhill, The University of Manchester, UK ................................................................................................................. 2259

Chapter 7.2 The Intersection of Gender, Information Technology, and Art / Linda Doyle, University of Dublin, Ireland; and Maryann Valiulis, University of Dublin, Ireland ................................................................................................................. 2266

Chapter 7.3 Gender-Based Attitudes Toward Technology / Konrad Morgan, University of Bergen, Norway; and Madeleine Morgan, University of Bergen, Norway ................................................................................................................. 2274

Chapter 7.4 Gender in Distance Education Technology / Colette Wanless-Sobel, University of Minnesota & Inver Hills Community College, USA ................................................................................................................. 2278

Chapter 7.5 Gender Differences in Information Technology Acceptance / Will Wai-kit Ma, Hong Kong University of Science and Technology, China and Hong Kong Shue Yan College, China; and Allan Hio-kau Yuen, The University of Hong Kong, China ................................................................................................................. 2287

Chapter 7.6 Discourses in Gender and Technology: Taking a Feminist Gaze / Sheila French, Manchester Metropolitan University, UK ................................................................................................................. 2296
Chapter 7.7 Theorizing Gender and Information Technology Research /
Eileen M. Trauth, The Pennsylvania State University, USA ................................................................. 2309

Chapter 7.8 Socio-Cognitive Model of Trust /
Rino Falcone, Institute for Cognitive Sciences and Technology, National Research Council of Italy, Italy; and Cristiano Castelfranchi, Institute for Cognitive Sciences and Technology National Research Council of Italy, Italy ............................................................................................................ 2316

Chapter 7.9 Information-Communications Systems Convergence Paradigm:
Invisible E-Culture and E-Technologies / Fjodor Ruzic, Institute for Informatics, Croatia .............. 2322

Chapter 7.10 IT Artefacts as Socio-Pragmatic Instruments: Reconciling the Pragmatic,
Semiotic, and Technical / Göran Goldkuhl, Linköping University &
Jönköping International Business School, Sweden;
and Pär J. Ågerfalk, University of Limerick, Ireland & Örebro University, Sweden ..................... 2341

Chapter 7.11 Ignorance is Bliss: The Effect of Increased Knowledge
on Privacy Concerns and Internet Shopping Site Personalization Preferences /
Thomas P. Van Dyke, The University of North Carolina Greensboro, USA ........................................ 2356

Chapter 7.12 The Function of Representation in a “Smart Home Context” /
Mats Edenius, Stockholm School of Economics, Sweden ............................................................................ 2376

Chapter 7.13 Towards a Meta-Model for Socio-Instrumental Pragmatism /
Peter Rittgen, University College of Borås, Sweden ........................................................................... 2390

Chapter 7.14 The Effect of Choice and Announcement Duration on
the Estimation of Telephone Hold Time / Philip Kortum, Rice University, USA;
Randolph G. Bias, The University of Texas at Austin, USA;
Benjamin A. Knott, U.S. Air Force Research Laboratory, USA;
and Robert G. Bushey, AT&T Laboratories, USA ................................................................................... 2404

Chapter 7.15 Towards Adaptive Security for Ubiquitous Computing Systems:
MOSQUITO and Serenity / Volkmar Lotz, SAP Research, France;
Luca Compagna, SAP Research, France; and Konrad Wrona, SAP Research, France ...................... 2424

Chapter 7.16 Trusting Computers Through Trusting Humans: Software Verification
in a Safety-Critical Information System / Alison Adam, University of Salford, UK;
and Paul Spedding, University of Salford, UK ...................................................................................... 2436

Chapter 7.17 Global Information Ethics: The Importance of Being Environmentally Earnest /
Luciano Floridi, Universita degli Studi di Bari, Italy and Oxford University, UK ......................... 2450
Chapter 7.18 Emotional Digitalization as Technology of the Postmodern: 
A Reflexive Examination from the View of the Industry / 
Claus Hohmann, Bergische Universitaet Wuppertal, Germany .................................................. 2462

Chapter 7.19 The Paleolithic Stone Age Effect? Gender Differences Performing 
Specific Computer-Generated Spatial Tasks / 
Geoffrey S. Hubona, Georgia State University, USA; 
and Gregory W. Shirah, National Aeronautics and Space Administration, USA ......................... 2473

Chapter 7.20 Optimality-Theoretic Lexical Mapping Theory: A Case Study of 
Locative Inversion / One-Soon Her, National Chengchi University, Taiwan ............................... 2499

Section VIII. Emerging Trends

This section highlights research potential within the field of human-computer interaction while exploring 
uncharted areas of study for the advancement of the discipline. Chapters within this section highlight 
the socio-semantic web, podcasts, and the emergence of increasingly intelligent user interfaces. These 
contributions, which conclude this exhaustive, multi-volume set, provide emerging trends and sugges-
tions for future research within this rapidly expanding discipline.

Chapter 8.1 Podcastia: Imagining Communities of Pod-People / Jonathan Cohn, UCLA, USA .... 2530

Chapter 8.2 Maximizing Web Accessibility Through User-Centered Interface Design / 
Soonhwa Seok, The University of Kansas, USA ............................................................................ 2542

Chapter 8.3 Voice-Enabled User Interfaces for Mobile Devices / 
Louise E. Moser, University of California, Santa Barbara, USA; 
and P. M. Melliar-Smith, University of California, Santa Barbara, USA ........................................ 2556

Chapter 8.4 Multilayered Approach to Evaluate Mobile User Interfaces / 
Maria de Fátima Queiroz Vieira Turnell, Universidade Federal de Campina Grande (UFCG), Brazil; 
José Eustáquio Rangel de Queiroz, Universidade Federal de Campina Grande (UFCG), Brazil; 
Danilo de Sousa Ferreira, Universidade Federal de Campina Grande (UFCG), Brazil .............. 2573

Chapter 8.5 Digital Imaging Trek: A Practical Model for Managing 
the Demand of the Digitally Enabled Traveller / Stephen C. Andrade, Johnson 
& Wales University, USA; and Hilary Mason, Johnson & Wales University, USA ................... 2590

Chapter 8.6 Intelligent User Interfaces for Mobile Computing / 
Michael J. O’Grady, University College Dublin, Ireland; 
and Gregory M. P. O’Hare, University College Dublin, Ireland ............................................. 2614

Chapter 8.7 Intelligent User Interfaces for Ubiquitous Computing / 
Rainer Malaka, Bremen University, Bremen .................................................................................. 2627
Chapter 8.8 Vive la Différence: The Cross-Culture Differences Within Us /
David Gefen, Drexel University, USA; Nitza Geri, The Open University of Israel, Israel;
and Narasimha Paravastu, Central State University, USA ...................................................... 2644

Chapter 8.9 Growing Up Wireless: Being a Parent and Being a Child in
the Age of Mobile Communication / Letizia Caronia, University of Bologna, Italy ................. 2655

Chapter 8.10 Politeness as a Social Computing Requirement /
Brian Whitworth, Massey University, New Zealand;
and Tong Liu, Massey University, New Zealand ........................................................................... 2675

Chapter 8.11 Neo-Symbiosis: The Next Stage in the Evolution
of Human Information Interaction /
Douglas Griffith, General Dynamics Advanced Information Systems, USA;
and Frank L. Greitzer, Pacific Northwest National Laboratory, USA ........................................ 2693

Chapter 8.12 Enabling Programmable Ubiquitous Computing Environments:
A Middleware Perspective / Christine Julien, The University of Texas at Austin, USA;
and Sanem Kabadayi, The University of Texas at Austin, USA ...................................................... 2708
Preface

The use of, engagement with, and study of technology has become the basis of modern life. As such, the field of human-computer interaction has emerged as an essential, multidisciplinary field that seeks to determine how humans interact with different interfaces and how these interfaces can be better designed, evaluated, and implemented to minimize barriers between human thought and computer behavior. As we continue to develop new and innovative technologies, we must also strive to more fully understand how these technologies impact humanity, both on a societal and individual level, and to remain aware of the latest in human-computer interaction research and exploration.

In recent years, the areas of study related to the interaction between people and technology have become innumerable. As a result, researchers, practitioners, and educators have devised a variety of techniques and methodologies to develop, deliver, and, at the same time, evaluate the effectiveness of the interfaces implemented and used in modern society. The explosion of methodologies in the field has created an abundance of new, state-of-the-art literature related to all aspects of this expanding discipline. This body of work allows researchers to learn about the fundamental theories, latest discoveries, and forthcoming trends in the field of human-computer interaction.

Constant technological and theoretical innovation challenges researchers to remain informed of and continue to develop and deliver methodologies and techniques utilizing the discipline’s latest advancements. In order to provide the most comprehensive, in-depth, and current coverage of all related topics and their applications, as well as to offer a single reference source on all conceptual, methodological, technical, and managerial issues in human-computer interaction, Information Science Reference is pleased to offer a four-volume reference collection on this rapidly growing discipline. This collection aims to empower researchers, practitioners, and students by facilitating their comprehensive understanding of the most critical areas within this field of study.

This collection, entitled Human Computer Interaction: Concepts, Methodologies, Tools, and Applications, is organized into eight distinct sections which are as follows: 1) Fundamental Concepts and Theories, 2) Development and Design Methodologies, 3) Tools and Technologies, 4) Utilization and Application, 5) Organizational and Social Implications, 6) Managerial Impact, 7) Critical Issues, and 8) Emerging Trends. The following paragraphs provide a summary of what is covered in each section of this multi-volume reference collection.

Section One, Fundamental Concepts and Theories, serves as a foundation for this exhaustive reference tool by addressing crucial theories essential to understanding human-computer interaction. Specific issues in human-computer interaction, such as ubiquitous computing, communities of practice, and online social networking are discussed in selections such as “Ubiquitous Computing and the Concept of Context” by Antti Oulasvirta and Antti Salovaara, “Sociotechnical Theory and Communities of Practice” by Andrew Wenn, and “Online Social Networking for New Researched Opportunities” by Lionel Mew. Within the selection “Personalization Techniques and Their Application,” authors Juergen Anke
and David Sundaram provide an overview of the personalization of information systems and the impact such an approach has on the usability of everything from e-learning environments to mobile devices. The selections within this comprehensive, foundational section allow readers to learn from expert research on the elemental theories underscoring human-computer interaction.

Section Two, Development and Design Methodologies, contains in-depth coverage of conceptual architectures and frameworks, providing the reader with a comprehensive understanding of emerging theoretical and conceptual developments within the development and utilization of tools and environments that promote interaction between people and technology. Beginning this section is the contribution “Measuring the Human Element in Complex Technologies” by Niamh McNamara and Jurek Kirakowski, which analyzes the role that user satisfaction has in shaping the design of products and the impact this has on developers. Similarly, “Design Methods for Experience Design” by Marie Jefsioutine and John Knight describes the authors’ framework for web site design—the Experience Design Framework. Other selections, such as “Content Personalization for Mobile Interfaces” by Spiridoula Koukia, Maria Rigou, and Spiros Sirmakessis and “Kinetic User Interfaces: Physical Embodied Interaction with Mobile Ubiquitous Computing Systems” by Vincenzo Pallotta, Pascal Bruegger, and Béat Hirshbrunner offer insight into particular methodologies for the design, development, and personalization of mobile user interfaces. From basic designs to abstract development, chapters such as “Designing and Evaluating In-Car User-Interfaces” by Gary Burnett and “Integrating Usability, Semiotic, and Software Engineering into a Method for Evaluating User Interfaces” by Kenia Sousa, Albert Schilling, and Elizabeth Furtado serve to expand the reaches of development and design techniques within the field of human-computer interaction.

Section Three, Tools and Technologies, presents extensive coverage of various tools and technologies that individuals interact, collaborate, and engage with every day. The emergence of social networking tools such as blogs and wikis is explored at length in selections such as “PDA Plagiarism, Instruction, and Blogs” by Michael Hanrahan, “Wikis as Tools for Collaboration” by Jane Klobas, and “Assessing Weblogs as Education Portals” by Ian Weber. Further discussions of the role of technology in learning are explored in chapters such as “How Technology Can Support Culture and Learning” by David Luigi Fuschi, Bee Ong, and David Crombie and “Facilitating E-Learning with Social Software: Attitudes and Usage from the Student’s Point of View” by Reinhard Bernsteiner, Herwig Ostermann, and Roland Staudinger. The latter of these two chapters discusses both the theoretical basis for the implementation of technology in an educational setting and the impact this implementation has on students. Ultimately, the authors conclude that online social networking has the potential to emerge as a useful tool for both students and teachers. The rigorously researched chapters contained within this section offer readers countless examples of the dynamic interaction between humans and technology.

Section Four, Utilization and Application, provides an in-depth analysis of the practical side of human computer interaction, focusing specifically on environments in which the relationship between humans and technology has been significant. Mobile device usage is highlighted in the selections “A De-Construction of Wireless Device Usage” by Mary R. Lind, “Localized User Interface for Improving Cell phone Users’ Device Competency” by Lucia D. Krisnawati and Restyandito, and ”Mobile Phone Use Across Cultures: A Comparison Between the United Kingdom and Sudan” by Ishraga Khattab and Steve Love. These selections offer conceptualization and analysis of the factors impacting wireless device usage, ultimately determining that many factors, such as culture, familiarity with the device itself, and ease of use influence an individual’s wireless device usage. Further contributions explore how human factors impact the successful use of technology in areas such as trend detection, veterinary medicine, mobile commerce, and web browsing. From established applications to forthcoming innovations, contributions in this section provide excellent coverage of today’s global community and demonstrate
how the interaction between humans and technology impacts the social, economic, and political fabric of our present-day global village.

Section Five, **Organizational and Social Implications**, includes a wide range of research pertaining to the organizational and cultural implications of humans’ reaction to technology. This section begins with a thorough analysis of the intersection of gender and technology in contributions such as “Gender, Race, Social Class, and Information Technology” by Myungsook Klassen and Russell Stockard, Jr., “Gender and the Culture of Computing in Applied IT Education” by Susan C. Herring, Christine Ogan, Manju Ahuja, and Jean C. Robinson, and “Gender Equalization in Computer-Mediated Communication” by Rosalie J. Ocker. Other issues that are surveyed within this section include the implication of cultural differences within Deborah Sater Carstens’ “Cultural Barriers of Human-Computer Interaction,” computer mediated communication in Bolanle A. Olaniran’s “Group Decision Making in Computer-Mediated Communication as Networked Communication: Understanding the Technology and Implications,” and community telecommunication networks in Sylvie Albert and Rolland LeBrasseur’s “Collaboration Challenges in Community Telecommunication Networks.” Overall, the discussions presented in this section offer insight into the implications of human computer interaction in both organizational and social settings, as well as provide solutions for existing problems and shortcomings.

Section Six, **Managerial Impact**, presents contemporary coverage of the managerial applications and implications of human computer interaction. This collection of research opens with “Social Impact of Virtual Networking” by Hakikur Rahman, which documents the emergence of the virtual enterprise and the impact such a structure has on social communication. Similarly, within the article “Human Factors for Networked and Virtual Organizations,” Vincent E. Lasnik emphasizes the role that human factors engineering must play in the future design of virtual and networked environments. Later contributions, such as “Knowledge Blogs in Firm Internal Use,” investigate knowledge transfer within and among organizations. Within this selection, authors Miia Kosonen, Kaisa Henttonen, and Kirsimarja Blomqvist identify factors for the implementation of “knowledge blogs” within organizations and explain why these tools can be used to encourage institutional memory, create identities, and to inform the organization itself. The comprehensive research in this section offers an overview of the major issues that practitioners, managers, end users and even consumers must address in order to remain informed about the latest managerial changes in the field of human computer interaction.

Section Seven, **Critical Issues**, presents readers with an in-depth analysis of the more theoretical and conceptual issues within this growing field of study by addressing topics such as security, ethics, and gender differences in technology adoption and use. Specifically, these topics are discussed in selections such as “Trusting Computers Through Trusting Humans: Software Verification in a Safety-Critical Information System” by Alison Adam and Paul Spedding and “Global Information Ethics: The Importance of Being Environmentally Earnest” by Luciano Floridi. Later selections, which include “Emotional Digitalization as Technology of the Postmodern: A Reflexive Examination from the View of the Industry,” review more novel issues, such as how the digitalization of emotions helps to bridge the gap between technology and humanity. Specifically, within this chapter, author Claus Hohmann identifies the emotion inherent in the design of new technologies and investigates how this has and will continue to impact human reaction. In all, the theoretical and abstract issues presented and analyzed within this collection form the backbone of revolutionary research in and evaluation of human-computer interaction.

The concluding section of this authoritative reference tool, **Emerging Trends**, highlights research potential within the field of human-computer interaction while exploring uncharted areas of study for the advancement of the discipline. “Communicating in the Information Society: New Tools for New Practices” by Lorenzo Cantoni and Stefano Tardini presents a framework for the latest digital communication tools and their implementation, while the evolution of the semantic web is analyzed in Cristian Peraboni
and Laura A. Ripamonti’s “Socio-Semantic Web for Sharing Knowledge.” The nature of podcasts and their role in encouraging collaboration and acting as an educational tool is explored in “Stay Tuned for Podcast U and the Data on M-Learning” by Deborah Vess and Michael Gass and “Podcastia: Imagining Communities of Pod-People by Jonathan Cohn. Other new trends, such as voice enabled interfaces for mobile devices, programmable ubiquitous computing environments, and intelligent user interfaces for mobile and ubiquitous computing are discussed in this collection. This final section demonstrates that humanity’s interaction with technology will continue to grow and evolve, shaping every facet of modern life.

Although the contents of this multi-volume book are organized within the preceding eight sections which offer a progression of coverage of important concepts, methodologies, technologies, applications, social issues, and emerging trends, the reader can also identify specific contents by utilizing the extensive indexing system listed at the end of each volume. Furthermore, to ensure that the scholar, researcher, and educator have access to the entire contents of this multi-volume set, as well as additional coverage that could not be included in the print version of this publication, the publisher will provide unlimited, multi-user electronic access to the online aggregated database of this collection for the life of the edition free of charge when a library purchases a print copy. In addition to providing content not included within the print version, this aggregated database is also continually updated to ensure that the most current research is available to those interested in human-computer interaction.

As technology continues its rapid advancement, the study of how to successfully design, implement and, ultimately, evaluate human reactions to and interactions with the modern world becomes increasingly critical. Innovations in the design of mobile devices, educational environments, and web sites have all been made possible through a more thorough understanding of how humans react to and engage with technological interfaces. Continued evolution in our understanding of the human-computer dynamic will encourage the development of more usable interfaces and models that aim to more thoroughly understand the theories of successful human-computer interaction.

The diverse and comprehensive coverage of human-computer interaction in this four-volume, authoritative publication will contribute to a better understanding of all topics, research, and discoveries in this developing, significant field of study. Furthermore, the contributions included in this multi-volume collection series will be instrumental in the expansion of the body of knowledge in this enormous field, resulting in a greater understanding of the fundamentals while also fueling the research initiatives in emerging fields. We at Information Science Reference, along with the editor of this collection, hope that this multi-volume collection will become instrumental in the expansion of the discipline and will promote the continued growth of human-computer interaction.
FUNDAMENTAL CONCEPTS AND THEORIES IN HUMAN COMPUTER INTERACTION

User-centered design begins with a thorough understanding of the needs and requirements of the users (Shneiderman, 1992). User needs analysis (or Knowledge Elicitation) and evaluation methods in HCI are a critical process to the success of requirements and design gathering (Maiden et al., 1995), usability testing, and user evaluation stages of software development (Zaphiris & Kurniawan, 2001).

Examples of knowledge elicitation methods often start with initial questionnaire feedback, requirements task walkthroughs, interviews techniques, and focus group sessions. They can rapidly scale upwards to more complex psychometric design and evaluation processes. For example, various fidelities of prototype construction, direct and indirect observation practices for monitoring user actions and response time comparisons, and methods for eliciting mental categorization models, that is, in distinguishing expert and non-expert technology usage patterns.

The measure of a good experience can vary from person to person; however the appropriate understanding of a usable design comes from gaining the knowledge that it is functional, efficient, and desirable to its intended audience (Kuniavksy, 2003).

John and Marks (1997) identify three key factors to assess the usability of an interface:

Usability is measured by the extent to which the intended goals of use of the overall system are achieved (effectiveness), the resources that have to be expended to achieve the intended goals (efficiency), and the extent to which the user finds the overall system acceptable (satisfaction) (John and Marks, 1997).

The usability of a system is also related to issues surrounding its accessibility. There is a broad range of users to whom Web-based services are directed, and the services provided ought to be accessible to them (e.g. visually, hearing, physically or cognitively impaired or even people with different experience of and attitudes towards technology).
In the United Kingdom, “The Disability Discrimination Act” (DDA) began to come into effect in December 1996 and brought in measures to prevent discrimination against people on the basis of disability. Part III of the Act aims to ensure that disabled people have equal access to products and services. Under Part III of the Act, businesses that provide goods, facilities, and services to the general public (whether paid for or free) need to make reasonable adjustments for disabled people to ensure they do not discriminate by:

- Refusing to provide a service;
- providing a service of a lower standard or in a worse manner; and
- providing a service on less favorable terms than they would to users without the disability.

There is a legal obligation on service providers to ensure that disabled people have equal access to Web-based products and services. Section 19(1) (c) of the Act makes it unlawful for a service provider to discriminate against a disabled person “in the standard of service which it provides to the disabled person or the manner in which it provides it”.

An important provision here is that education is not covered by the DDA, but by separate legislation, titled the Special Educational Needs and Disability Act 2001 (SENDA). This Act introduces the right for disabled students not to be discriminated against in education, training, and any services provided wholly or mainly for students, and for those enrolled in courses provided by “responsible bodies”, including further and higher education institutions and sixth form colleges. Student services covered by the Act can include a wide range of educational and non-educational services, such as field trips, examinations and assessments, short courses, arrangements for work placements and libraries, and learning resources. In a similar wording to the DDA, SENDA requires responsible bodies to make reasonable adjustments so that people with disabilities are not at a substantial disadvantage.

DEVELOPMENT AND DESIGN METHODOLOGIES

There are many different elicitation and usability/accessibility evaluation techniques (Cooke, 1994) and selecting the “right” technique in a particular situation is not trivial.

Burge’s Table of Knowledge Elicitation Methods (Burge, 2001) provides an extensive comparative view of almost all the common KE techniques found in HCI.

In addition, usability and accessibility evaluation techniques are often grouped into two broad areas: user-based (that often include user testing) and expert based (that often include heuristic evaluation and cognitive walkthrough) techniques.

King et al. (2004) presented what they called “An incremental usability and accessibility evaluation framework for digital libraries”. Their framework is broken down into seven key activities and addresses all stages of a design of a system.

**Activity 1: Conduct Query - Requirement Gathering**
Identify satisfaction levels of current users of the system and establish key positive and negative aspects of the interface, what features they would like to see, and so forth.

**Activity 2: Analysis**
Evaluate current findings and identify issues not yet addressed
Activity 3: Perform Empirical (user) Evaluations
We regard user testing as the strongest evaluation technique, allowing us to identify real user problems by observing users interacting with the system. Retrospective focus groups or interviews conducted after the evaluations also provide a volume of qualitative data.

Activity 4: Analysis
Establish key problems and assess if any areas of the service have not been covered by user evaluations

Activity 5: Expert Evaluations
Appropriate modification of expert evaluation techniques maybe required so that they supplement previous evaluation findings, and address any areas or issues that have not as yet been covered

Activity 6: Analysis
Analyze all data identifying key issues that need to be addressed in the redesign of the service.
Establish new usability and accessibility goals for the design

Activity 7: Iterative Process
Re-conduct all stages in the iterative framework to evaluate redesign

We now describe some of the key methods that are associated with the above mentioned framework.

Interviewing

This query-based process elicits from users knowledge on a set information topic based on their expertise in the domain in question. It is useful for obtaining behavioral reasoning and background knowledge. Interviews can be categorized as structured or unstructured. Structured interviews elicit limited responses from users, by using a series of closed questions that have to be answered based on given solutions. This enables the user data to be analysed quicker but is not necessarily as informative as unstructured (open ended) interviews.

Preece et al. (1994) suggests that interview processes are most effective as semi-structured based on a series of fixed questions that gradually lead into more in-depth user needs and requirements understanding, then allowing for open ended responses to possibly create new dynamic questions based on prior structured responses (Macaulay, 1996). On-site stakeholder interviews allows researchers to bring about a vivid mental model of how users work with existing systems and how new systems can support them (Mander and Smith, 2002).

Interviews are useful when combined with surveys or questionnaires, as they can be used to improve the validity of data by clarifying specific issues that were raised in the survey or questionnaire.

Surveys

In conducting surveys, three things are necessary: a) the set of questions, b) a way to collect responses, and c) access to the demographics group you wish to test. There are several widely reported templates for acquiring different types of user data, such as the Quality of User Interface Satisfaction (QUIS) by Chin et al. (1988) and the Computer System Usability Questionnaire (CSUQ) by IBM with Lewis et al. (1995).
Surveys can be similarly open and closed question based, but also allow us to enquire scalar results giving indicators of quality in positive and negative statements. Self-filling surveys can be time efficient to deploy, and results from closed questions can be fast to analyze.

Open questions tend to elicit unanticipated information which can be very useful for early design. Existing survey sampling techniques include face-to-face, paper- and pencil-based, telephone surveys where the researcher will fill in the results (which becomes more of an interview style) but there is modern interest in computer assisted and Web-based surveying techniques.

Focus Groups

This activity is useful for eliciting cross-representative domains of knowledge from several stakeholders/users, in an open discussion format. Sessions are often moderated and tend to be informal by nature, centering on the creation of new topics from open questions.

Evidence shows that the optimal number needed for a mixed experience focus group is between five to eight participants, with group size being inversely related to the degree of participation (Millward, 1995).

Observation

Observation methods elicit user knowledge from the way users interact with a prototype or a final product. It can be direct, whereby a researcher is present and can steer users to particular points in an interaction. This tends to utilize video camera equipment and note taking to successfully enquire the timeline of user actions that is “getting from point A to point D may require steps B or C”.

The other model of observation is indirect, whereby all user actions are captured electronically. The researcher has to maintain co-operation between users and should only pose questions if clarification is needed.

Paper Prototyping

There are several approaches to paper prototypes, enabling users to create quick and partial designs of their concepts. It is often used in early stages of the design processes. Though the methodology lacks standardization, Rettig (1994) distinguishes between high-tech and low-tech views, and the more commonly modeled categories are of low, medium and high fidelity prototypes (Greenberg, 1998). Rudd et al. (1996) also distinguishes prototypes according to horizontal and vertical prototypes, with vertical representing deep functionality of a limited view to the final output, and horizontal giving a wide overview of the full functionality of the system but with a weaker depth of understanding. Hall (2001) discusses the benefits of using various levels of fidelities of prototypes.

Cognitive Walkthrough

Cognitive Walkthrough is an expert based evaluation technique that steps through a scenario/task by focusing on the users’ knowledge and goals. The expert evaluator first starts with descriptions of: the prototype interface, the task(s) from the user’s perspective, the correct sequence of actions needed to complete the task using the prototype and any assumptions about the characteristics of the user.

Then the evaluator walks through the tasks using the system, reviewing the actions that are necessary and attempting to predict how the users will behave.
A series of key questions are used throughout each sub-task evaluation:

- Will the user be trying to achieve the correct effect?
- Will the user know that the correct action is available?
- Will user know that the correct action will achieve the desired effect?
- If the correct action is taken, will the user see that things are going okay?

**Heuristic Evaluation**

Heuristic Evaluation is an expert review technique where experts inspect the interface to judge compliance with established usability principles (the ‘heuristics’)

Heuristic Evaluation is usually conducted in a series of four steps:

- Prepare: create a prototype to evaluate; select evaluators; prepare coding sheets to record problems
- Determine approach: either set typical user tasks (probably the most useful approach) or allow evaluators to establish their own tasks or conduct an exhaustive inspection of entire interface
- Conduct the evaluation: evaluators inspect interface individually to identify all violations of heuristics (the usability problems); record the problem (feature and location), severity (based on frequency, impact, criticality/cost) and heuristic violated
- Aggregate and analyze results: group similar problems; reassess severity; determine possible fixes

**Hierarchical Task Analysis (HTA)**

Hierarchical task analysis (HTA) is an analytic tool commonly used to describe people’s actions when interacting with the artifacts. We can analyze people’s work or leisure activities by focusing on what people do, their goals, mediating artifacts and their background knowledge. The primary use of HTA is to understand, clarify and organize our knowledge about existing system and work. It is applied in design and evaluation of the interactive system.

Essentially, HTA is concerned with the structure of tasks people are engaged in and how the tasks can be broken down into steps of sub-task hierarchies and how the order of sub-tasks can be described meaningfully.

In HTA, we break down a task from top to bottom, showing a hierarchical relationship amongst the tasks. This allows us to view the task at different levels of details

A task is the set of activities in which a user engages to achieve a goal. In other words, a task consists of a sequence of actions performed to achieve a goal. A goal is defined as the desired state of a system.

Usually HTA involves collecting information using data collection techniques (e.g. interviews, questionnaires, observations) and then analyzing it.

HTA can be presented as text or diagrams to show the hierarchy.

There are generally eight steps for task analysis:

- Define the purpose of analysis and the boundary of the system.
- Identify user groups, select representatives, and identify main tasks of concern.
- Design and conduct data collection to elicit information about these tasks.
- Identify the goals (and sub-goals) that users are trying to achieve, the steps they engage in, their rationale, and the information resources they use.
• Obtain information from documentation, interviews, questionnaires, focus groups, observation, ethnography, experiments, and so forth.
• Analyze the data to model specific instances of tasks initially, and then consider decomposition of tasks, balance of the model and stopping rules.
• Generalize across the specific task models to create a generic (or composite) task model: From each task model for the same goal produce a generic model that includes all the different ways of achieving the goal.
• Check the models with users, other stakeholders, analysts, and iterate the analysis process.

TOOLS AND TECHNOLOGIES

HCI community approaches design problems using different tools to help identify the users, their needs and behaviors, user interface problems. Various kinds of tools have been developed to tackle different research objectives. We can categorize these tools into three major categories: hardware, software and analytic tools. In this section we will describe an example of tool for each category

Eye Tracking

Eye tracking has been used for a very long time in psychology, focusing on recording eye movements while reading. However, in the 1980’s researchers began to incorporate eye tracking into issues of human computer interaction. As technological tools such as the Internet, e-mail, and videoconferencing evolved into viable means of communication and information sharing during the 1990’s and beyond, researchers started using eye tracking in order to answer question about usability. Eye tracking technologies have been widely used as a proxy for users’ attention and the eye movement data gathered helps to understand where people focus attention, and in what order before they make a selection in their interactions with computer interfaces.

Goldberg and Kotval (1999) made a convincing argument for the use of eye-movement data in interface evaluation and usability testing. They claim that “Interface evaluation and usability testing are expensive, time-intensive exercises, often done with poorly documented standards and objectives. They are frequently qualitative, with poor reliability and sensitivity”. The motivating goal for their research work assessing eye movements as an indicator of interface usability was the provision of an improved tool for rapid and effective evaluation of graphical user interfaces.

They performed an analysis of eye movements (using interface designers and typical users) in order to assess the usability of an interface for a simple drawing tool. Comparing a ‘good’ interface with well-organized tool buttons to a ‘poor’ interface with a randomly organized set of tool buttons, the authors could show that the good interface resulted in shorter scan paths that cover smaller areas. The chief merit of this study was the introduction of a systematic classification of different measures for evaluating the usability of user interfaces based on eye movement data. These measures were grouped as follows: Measures of Processing (Number of fixations, Fixation Duration, Fixation / Saccade ratio, Scanpath Length, Scanpath Duration, Convex Hull Area, Spatial Density, Transition Matrix, Number of Saccades, Saccadic Amplitude), Other Measures (Backtrack, On-target / all-target fixations, Post-target fixations).

Usability Testing Software

Due to the escalating importance of HCI in software and Web design, some tools have been developed to assist the process of usability testing. Traditionally, usability testing involves the use of video cameras,
screen capture tools, microphones, and so forth. One of the main challenges lies in the integration of the media in various formats in a coherent way. Together with cheap computer hardware, usability testing software overcomes this problem by providing a coherent solution, in which Webcam, microphone and screen capture software operate concurrently under one system managed by the usability software. The output is seamless presentation of all media file which can be edited and annotated.

Typically, usability testing tools (hardware and software) consists of the following functionalities:

**User experience recording:**
The most common activity in usability testing is probably recording user performing tasks with the software or Web site under testing. This includes video recording (of the user), screen capture and voice recording (verbal protocol). With the usability testing tools, we can set the tasks needed to be performed, record the performance and administer questionnaires in an integrated environment.

**Observation and logging:**
Some usability tools support the connected of network computers thus allowing multiple observers to monitor the users and annotate the videos collaboratively. Furthermore, most tools can also log the mouse click and keyboard pressing.

**Analysis**

Although still limited to basic visualization, usability tools can support data analysis by calculating aggregate usability metrics for users or for tasks. For instance, we are able to quickly identify tasks with low usability metrics and thus focus on improving the design relevant to the tasks.

This reduces the amount of work and time significantly and it makes usability testing less costly.

**UTILIZATION AND APPLICATION OF HUMAN COMPUTER INTERACTION**

We now describe a number of key areas where HCI can have a practical application.

**Computer–Augmented Environments**

One application area in which HCI plays an important role is the computer-augmented environments, or commonly known as augmented reality or mixed reality. It refers to the combination of real world and computer-generated data visualization. In other words it is an environment which consists of both real world and virtual reality. For instance, a surgeon might be wearing goggles with computer generated medical data projected on it. The goggles are said to augment the information the surgeon can see in the real world through computer visualization. Therefore, it is not difficult to see the connection of augmented reality with ubiquitous computing and wearable computers.

Since its inception, augmented reality has had an impact on various application domains. The most common use is probably the support of complex tasks in which users need to perform a series of complicated actions while having access to large amount of information at the same time, such as surgery, assembly and navigation. Apart from these, augmented reality is also used for learning and training, such as flight and driving simulations.

Augmented reality implementation usually requires additional devices for input and output in order to integrate computer generated data into real world:
A Cave Automatic Virtual Environment multi-user, room-sized, high-resolution, 3D video and audio immersive environment in which the virtual reality environment is projected onto the walls. The user wearing a location sensor can move within the display boundaries, and the image will move with and surrounds the user.

A head-up display (HUD) is a transparent display that presents data without obstructing the user’s view. It is usually implemented on vehicles in which important information is projected directly in the driver’s viewing field. Thus the user does not need to shift attention between what is going on in the real world and the instrumental panel.

A head-mounted display is a display device, worn on the head or as part of a helmet that has a small display optic in front of one or both eyes.

Some of these devices have become commercially available and increasingly affordable. The challenge of HCI lies in the design of information visualisation which is not obtrusive to the users’ tasks.

**Computer-Based Learning**

A lot of effort has been put in coupling learning and technology to design effective and enjoyable learning. Various areas, namely e-learning, computer-based learning, serious games, etc have emerged, hoping to utilize the interactive power of computers to enhance teaching and learning experience. A myriad of design strategies have been proposed, implemented and evaluated, these include the early use of computer in presentation, drill and practice (the behaviourist paradigm), tutorials (cognitivist paradigm), games, story telling, simulations (constructivist paradigm), and so forth. As we progress from behaviorist to constructivist, we notice an explosion of user interface complexity. For instance, drill and practice programs usually consist on a couple of buttons (next, previous buttons, buttons for multiple choice, etc) while simulations could involve sophisticated visualization (outputs) and various user interface elements for manipulating parameters (input). Recently computer-based learning has moved from single user offline environments to online network spaces in which a massive number of users can interact with each other and form a virtual learner community. This social constructivist learning paradigm requires not only traditional usability treatment, but also sociability design in which the system includes not only the learning tools, but other sociability elements such as rules and division of labors.

**Information Visualization**

Information visualization is an area in HCI which can be related to many other areas such as augmented reality just described before. Most modern computer applications deal with visual outputs. Graphical user interface has almost entirely replaced command-based interaction in many domains. Information visualization can be defined as “the use of computer supported, interaction, visual representations of abstract data to amplify cognition” (Shneiderman, 1992). To amplify cognition means that visualization shifts cognitive loads to the perceptual system, thus expanding working memory and information storage.

Visualization provides a more perceptually intuitive way of viewing raw data, thus allowing users to identify relevant patterns which would not have been identified in raw data.

Therefore, it has a huge impact on many applications domains, ranging from engineering, education, various fields in science, and so forth.

In HCI, the most obvious application is the use of visualization is in the design of graphical user interface that allows more intuitive interaction between human and computers. Various innovative interaction styles have been developed such as WIMP (window, icon, menu, pointing device) which is so familiar in today’s software. Three-dimensional graphics are also emerging although currently they
are mostly used in computer games and computer-aided design. One recent example of 3D graphical interface is the new windows navigation and management known as Windows Flip 3D in Windows Vista which allows the user to easily identify and switch to another open window by displaying 3D snapshot thumbnail preview of all windows in stack.

Today, Information visualization is not only about creating graphical displays of complex information structures. It contributes to a broader range of social and collaborative activities. Recently, visualization techniques have been applied on social data to support social interaction, particularly in CMC. This area is known as social visualization by (Donath, Karahalios, & Viégas, 1999). Other technique such as social network analysis has also become increasingly important in visualization social data.

Other areas where HCI plays an important role include: Intelligent and agent systems; Interaction design; Interaction through wireless communication networks; Interfaces for distributed environments; Multimedia design; Non–verbal interfaces; Speech and natural language interfaces; Support for creativity; Tangible user interfaces; User interface development environments and User support systems.

ORGANISATIONAL AND SOCIAL IMPLICATIONS OF HUMAN COMPUTER INTERACTION

The application of HCI can have an effect of organisational and social dimensions. For example, the area of computer supported collaborative work (CSCW) explores the effect the introduction of technology can have an effect on the organisational structure and the way of work of companies and organisations. Similarly the study of how we use technology to communicate with each other is gaining strong interest in the HCI research community.

The expansion of the Internet has resulted in an increase in the usefulness of Computer Mediated Communication (CMC) and the popularity of online communities. It is estimated that 25% of Internet users have participated in chat rooms or online discussions (Madden & Rainie, 2003).

It is by now no secret how vital the Internet was, is, and will continue to be in our lives. One of the most important characteristics of this medium is the opportunities it offers for human-human communication through computer networks. As Metcalfe (1992) points out, communication is the Internet’s most important asset. E-mail is just one of the many modes of communication that can occur through the use of computers. Jones (1995) points out that through communication services, like the Internet, Usenet and bulletin boards, online communication has for many people supplanted the postal service, telephone and even the fax machine. All these applications where the computer is used to mediate communication are called Computer-Mediated Communication (CMC).

December (1997) defines CMC as “the process by which people create, exchange, and perceive information using networked telecommunications systems (or non-networked computers) that facilitate encoding, transmitting, and decoding messages”. He emphasizes that studies of CMC view this process from different interdisciplinary theoretical perspectives (social, cognitive/psychological, linguistic, cultural, technical, political) and often draw from fields such diverse as human communication, rhetoric and composition, media studies, human-computer interaction, journalism, telecommunications, computer science, technical communication and information studies.

Online communities emerge through the use of CMC applications. The term online community is multidisciplinary in nature, means different things to different people, and is slippery to define (Preece, 2000). For purposes of a general understanding of what online communities are, Rheingold’s definition of online communities is presented:
Online communities are also often referred to as cyber societies, cyber communities, Web groups, virtual communities, Web communities, virtual social networks and e-communities among several others.

The cyberspace is the new frontier in social relationships, and people are using the Internet to make friends, colleagues, lovers, as well as enemies (Suler, 2004). As Korzeny pointed out, even as early as 1978, online communities are formed around interests and not physical proximity (Korzeny, 1978). In general, what brings people together in an online community is common interests such as hobbies, ethnicity, education, beliefs. As Wallace (1999) points out, meeting in online communities eliminates prejudging based on someone’s appearance, and thus people with similar attitudes and ideas are attracted to each other.

It is estimated that as of September 2002 there are over 600 million people online (Nua Internet Surveys, 2004). The emergence of the so-called “global village” was predicted years ago (McLuhan, 1964) as a result of television and satellite technologies. However, it is argued by Fortner (1993) that “global metropolis” is a more representative term (Choi & Danowski, 2002). If one takes into account that the estimated world population of 2002 was 6.2 billion (U.S. Census Bureau, 2004), then the online population is nearly 10% of the world population – a significant percentage which must be taken into account when analyzing online communities. In most online communities, time, distance and availability are no longer disseminating factors. Given that the same individual may be part of several different and numerous online communities, it is obvious why online communities keep increasing in numbers, size and popularity.

Preece et al. (2002) states that an online community consists of people, a shared purpose, policies and computer systems. She identifies the following member roles:

- **Moderators and mediators**: who guide discussions/serve as arbiters
- **Professional commentators**: who give opinions/guide discussions
- **Provocateurs**: who provoke
- **General Participants**: who contribute to discussions
- **Lurkers**: who silently observe

CMC has its benefits as well as its limitations. For instance, CMC discussions are often potentially richer than face-to-face discussions. However, users with poor writing skills may be at a disadvantage when using text-based CMC (Scotcit, 2003).

**Examples of CMC and Online Communities**

Examples of CMC include asynchronous communication like e-mail and bulletin boards; synchronous communication like chatting; and information manipulation, retrieval and storage through computers and electronic databases (Ferris, 1997).

When it comes to Web site designers, choosing which CMC to employ (for instance, forum or chat-room) is not a matter of luck or randomness. Selecting the right CMC tool depends on a lot of factors. For example, in the case of e-learning, the choice of the appropriate mode of CMC will be made by asking and answering questions such as (Bates, 1995; CAP, 2004; Heeren, 1996; Resier and Gagne, 1983):
• Are the users spread across time zones? Can all participants meet at the same time?
• Do the users have access to the necessary equipment?
• What is the role of CMC in the course?
• Are the users good readers/writers?
• Is the activities time independent?
• How much control is allowed to the students?

Audio-conferencing is a real time communication mechanism, since the communication happens synchronously. Depending on the application, text chat and graphics may also be supported. Videoconferencing, like audio-conferencing, offers a useful mode of communication, but has the added benefit of being able to also see the participants, instead of just hearing them.

IRC and chats also support synchronous communication, since they enable the users to carry out conversations through the use of text messaging. MUDs build on chats by providing avatars and graphical environments where the users can engage in interactive fantasy games (Preece, 2000).

World Wide Web web sites are usually asynchronous, providing community information and links to other sites, but sometimes also have synchronous software, like chats, embedded in them (Preece, 2000).

E-mail is an asynchronous mode of communication usually in the form of text. However, the ability to add attachments to e-mail messages makes it possible for audio, video and graphics to be used also. Voice mail is an expansion of e-mail whereby users may record themselves speaking a message and then send that voice file to their contact, instead of typing it. Newsgroups, like e-mail, provide an asynchronous mode of communication, but unlike e-mail where the messages come to the users, it is a “pull” technology meaning the users must go to the UseNet groups themselves (Preece, 2000). Finally, discussion boards, also referred to as forums or bulletin boards provide an asynchronous mode of communication where the users post messages for others to see and respond at their own time.

Preece (2000) describes in detail some of these types of CMC and their different characteristics. In this chapter, we focus on Wiki and Online Virtual Game Environments which in our view provide a set of new, novel modes of communication and online community building systems.

Analyzing Online Communities: Frameworks and Methodologies

There are various aspects and attributes of CMC that can be studied to help us better understand online communities. For instance, the analysis of the frequency of exchanged messages and the formation of social networks, or, the analysis of the content of the exchanged messages and the formation of virtual communities. To achieve such an analysis a number of theoretical frameworks have been developed and proposed. For example Henri (1992) provides an analytical model for cognitive skills that can be used to analyze the process of learning within messages exchanged between students of various online e-learning communities. Mason’s work (1991) provides descriptive methodologies using both quantitative and qualitative analysis. Furthermore, five phases of interaction analysis are identified in Gunawardena et al.’s model (1997):

• Sharing/Comparing of Information
• The Discovery and Exploration of Dissonance or Inconsistency among Ideas, Concepts or Statements
• Negotiation of Meaning/Co-Construction of Knowledge
• Testing and Modification of Proposed Synthesis or Co-Construction
• Agreement Statement(s)/Applications of Newly Constructed Meaning
In this section we provide a description of some of the most commonly used online community evaluation techniques as well as their weaknesses and strengths.

**Studying CMC**

All of the already mentioned methods can be used to evaluate the usability and accessibility of the online community. But, apart from usability and accessibility we often also want to evaluate the user experience and the sociability of the interface. We describe below some of the methods that can assist us in this:

**Personas**

Findings from interviews and questionnaires can be further used as a basis for developing user profiles using personas. A persona is a precise description of the user of a system, and of what he/she wishes to accomplish. (Cooper, 1999). The specific purpose of a persona is to serve as a tool for software and product design. Although personas are not real people, they represent them throughout the design stage and are best based on real data collected through query based techniques.

Personas are rich in details, include name, social history and goals, and are synthesized from findings through the use of query based techniques with real people (Cooper, 1999). The technique takes user characteristics into account and creates a concrete profile of the typical user (Cooper, 1999).

For online communities, personas can be used to better understand the participants of the community and their background. Personas can also be used as a supplement to Social Network Analysis (described later in this chapter) to get a greater overview of the characteristics of key participants of a community. Using personas, Web developers gain a more complete picture of their prospective and/or current users and are able to design the interfaces and functionality of their systems, to be more personalized and suited for the communication of the members of their online communities.

Advantages of personas include: can be used to create user scenarios; can be anonymous protecting user privacy; represent the user stereotypes and characteristics.

Disadvantages of personas include: if not enough personas are used, users are forced to fall into a certain persona type which might now accurately represent them; time-consuming.

**Log Analysis**

A log, also referred to as Web-log, server log or log-file is in the form of a text file and is used to track the users’ interactions with the computer system they are using. The types of interaction recorded include key presses, device movements and other information about the user activities. The data is collected and analyzed using specialized software tools and the range of data collected depends on the log settings. Logs are also time stamped and can be used to calculate how long a user spends on a particular task or how long a user is lingered in a certain part of the Web site (Preece, Rogers & Sharp, 2002). In addition, an analysis of the server logs can help us find out: when people visited the site, the areas they navigated, the length of their visit, the frequency of their visits, their navigation patterns, from where they are connected and details about the computer they are using.

Log analysis is a useful and easy to use tool when analyzing online communities. For example, someone can use log analysis to answer more accurately questions like student attendance of an online learning community. Furthermore, logs can identify the Web pages users spend more time viewing, and also the paths that they used. This helps identify the navigation problems of the Web site, but also gives
a visualization of the users’ activities in the virtual communities. For instance, in the case of e-learning communities, the log files will show which students are active in the CMC postings even if they are not active participants (few postings themselves), but just observing the conversations. Preece (2003) notes that data logging does not interrupt the community, while at the same time can be used to examine mass interaction.

Advantages of Logs (Preece et al., 2002): helps evaluators analyze users behavior; helps evaluators understand how users worked on specific tasks; it is unobtrusive; large volumes of data can be logged automatically.

Disadvantages of Logs (Preece et al., 2002): powerful tools are needed to explore and analyze the data quantitatively and qualitatively; user privacy issues.

Content and Textual Analysis

Content analysis is an approach to understanding the processes that participants engage in as they exchange messages. There have been several frameworks created for studying the content of messages exchanged in online communities. Examples include work from Archer, Garrison, Anderson & Rourke (2001), Gunawardena, Lowe, and Anderson’s (1997) model for examining the social construction of knowledge in computer conferencing, Henri’s (1992) content analysis model and Fahy et al.’s (2001) Transcript Analysis Tool (TAT) which is described in more detail below.

The TAT focuses on the content and interaction patterns at the component level of the transcript (Fahy et al., 2001). After a lengthy experience with other transcript tools and reviews of previous studies Fahy et al. (2001), chose to adapt Zhu’s (1996) analytical model for the TAT. Zhu’s model (1996) examines the forms of electronic interaction and discourse, the forms of participation and the direction of participant interaction in computer conferences. The TAT also contains echoes of Vygotskian theory, primarily those dealing with collaborative sense making, social negotiation and proximal development (Cook & Ralston, 2003). The TAT developers have come up with the following strategic decisions (Fahy, 2003): The sentence is the unit of analysis; the TAT is the method of analysis; interaction is the criterion for judging conference success and topical progression (types and patterns).

The TAT was designed to permit transcript content to be coded reliably and efficiently (Fahy et al., 2001), while the advantages of TAT are (Fahy, 2003; Cook & Ralston, 2003; Fahy et al., 2001): It reveals interaction patterns that are useful in assessing different communication styles and online behavioral preferences among participants; It recognizes the complexity of e-conferences and measures the intensity of interaction; It enables the processes occurring within the conferences to be noted and recorded; It probes beyond superficial systems data, which mask the actual patterns of discussion; It relates usefully to other work in the area; It discriminates among the types of sentences within the transcript; It reflects the importance of both social and task-related content and outcomes in transcript analysis research.

The unit of analysis of the TAT is the sentence. In the case of highly elaborated sentences, the units of analysis can be independent clauses which, punctuated differently, could be sentences (Fahy, 2003). Fahy et al. (2001), have concluded that the selection of message-level units of analysis might partially explain problematic results that numerous researchers have had with previous transcript analysis work. They also believe that the finer granularity of sentence-level analysis results in several advantages (Fahy, 2003; Ridley & Avery, 1979): Reliability; Ability to detect and describe the nature of the widely varying social interaction, and differences in networking pattern, in the interactive behavior of an online community, including measures of social network density and intensity; Confirmation of gender associations in epistolary/expository interaction patterns, and in the use of linguistic qualifiers and intensifiers.
Social Network Analysis (SNA)

“Social Network Analysis (SNA) is the mapping and measuring of relationships and flows between people, groups, organisations, computers or other information/knowledge processing entities. The nodes in the network are the people and groups while the links show relationships or flows between the nodes. SNA provides both a visual and a mathematical analysis of human relationships” (Krebs, 2004, pp.1). Preece (2000) adds that it provides a philosophy and a set of techniques for understanding how people and groups relate to each other, and has been used extensively by sociologists (Wellman, 1982; Wellman 1992), communication researchers (Rice, 1994; Rice et al., 1990) and others. Analysts use SNA to determine if a network is tightly bounded, diversified or constricted; to find its density and clustering; and to study how the behavior of network members is affected by their positions and connections (Garton, Haythornthwaite & Wellman, 1997; Wellman, 1997; Henneman, 1998; Scott, 2000). Network researchers have developed a set of theoretical perspectives of network analysis. Some of these are (Bargotti, 2002):

- Focus on relationships between actors than the attributes of actors.
- Sense of interdependence: a molecular rather atomistic view.
- Structure affects substantive outcomes.
- Emergent effects.

“The aim of social network analysis is to describe why people communicate individually or in groups” (Preece, 2000, pp. 183), while the goals of SNA are (Dekker, 2002):

- To visualize relationships/communication between people and/or groups using diagrams.
- To study the factors which influence relationships and the correlations between them?
- To draw out implications of the relational data, including bottlenecks.
- To make recommendations to improve communication and workflow in an organisation.

Preece (2002) and Beidernikl & Paier (2003) list the following as the limitations of SNA:

- More theory that speaks directly to developers of online communities is needed
- The data collected may be personal or private.
- The analysis of the data is quantitative and specific to the particular network, while common survey data are qualitative and generalize answers on the parent population.

It is also worth pointing out that network analysis is concerned about dyadic attributes between pairs of actors (like kinship, roles, and actions), while social science is concerned with monadic attributes of the actor (like age, sex, and income).

There are two approaches to SNA:

**Ego-centered analysis**: Focuses on the individual as opposed to the whole network, and only a random sample of network population is normally involved (Zaphiris, Zacharia, & Rajasekaran, 2003). The data collected can be analyzed using standard computer packages for statistical analysis like SAS and SPSS (Garton, Haythornthwaite, & Wellman, 1997).
Whole network analysis: The whole population of the network is surveyed and this facilitates conceptualization of the complete network (Zaphiris et al., 2003). The data collected can be analyzed using microcomputer programs like UCINET and Krackplot (Garton et al., 1997).

The following are important units of analysis and concepts of SNA (Garton et al., 1997; Wellman, 1982; Hanneman, 2001; Zaphiris et al, 2003; Wellman, 1992):

- Nodes: The actors or subjects of study.
- Relations: The strands between actors. They are characterized by content, direction, and strength.
- Ties: Connect a pair of actors by one or more relations.
- Multiplexity: The more relations in a tie, the more multiplex the tie is.
- Composition: This is derived from the social attributes of both participants.
- Range: The size and heterogeneity of the social networks.
- Centrality: Measures who is central (powerful) or isolated in networks.
- Roles: Network roles are suggested by similarities in network members’ behavior.
- Density: The number of actual ties in a network compare to the total amount of ties that the network can theoretically support.
- Reachability: In order to be reachable, connections that can be traced from the source to the required actor must exit.
- Distance: The number of actors that information has to pass through to connect the one actor with another in the network.
- Cliques: Sub-sets of actors in a network, who are more closely tied to each other than to the other actor who are not part of the subset.

Social Network Analysis is a very valuable technique when it comes to analyzing online communities as it can provide a visual presentation of the community and more importantly it can provide us with qualitative and quantitative measures of the dynamics of the community.

EMERGING TRENDS IN HUMAN COMPUTER INTERACTION

Computer Game, Play and Immersion

Researchers from various areas have begun exploring the role of emotion in human activities. This research has proven to yield important results that not only deepen our understanding on human emotion, but potentially improves the design and development of artifacts. This goes without saying that the topic of emotion is becoming increasingly important in HCI. Probably one of the most studied domains in emotional design is the computer game.

Computer games have been widely recognized as the software which is potentially addictive due to their capability to engage and immerse the players for hours of game play. Therefore, it can be claimed that emotion is vital to maintain players’ focus and to create enjoyable experiences.

Unlike work-oriented activity (and thus work-oriented software that mediate them), game play traditionally does not focus on productive outcome. In this case, usability of game play cannot be understood in a traditional sense. Already new metrics of usability (or playability) have been proposed for designing playful artifacts/software.
Some effort has also been taken to incorporate game elements into productive activities. For instance, a project has been carried out to use games to label the contents of images meaningfully. Others have used games for education and training. An area of research, known as serious games, is expanding quickly to study productive games.

Recently, playability design has undergone a major transformation as games are becoming increasingly collaborative with the emergence of massively multiplayer online role-playing games (MMORPGs).

These games are becoming one of the most interesting interactive media of computer-mediated communication and networked activity environments (Taylor, 2002). Understanding the pattern of participation in these game communities is crucial, as these virtual communities function as a major mechanism of socialization of the players.

Some usability studies have shown that MMORPG design should incorporate what is known as sociability. For instance research has found that game locations can be designed to encourage different styles of social interactions

**CMC, Online Community and Social Computing**

Secondly, with the development of high performance computer networks, the use of computers is becoming increasingly collaborative. Therefore, topics such as CSCW, CMC, or social computing in general will continue to thrive.

One of the studied issues in this research topic is the use of non-verbal cues in the CMC technology. Some newer CMC media have attempted to address this issue through the implementation of video streaming, although a more common way is the use of “emoticons” that allows the users to express their emotions through graphical icons that show symbolic facial expressions.

Identity and anonymity is another popular topic regarding CMC since it is possible for users to hide their real identity simply by choosing a different name. In most cases, even the administrators do not know their real identity. Furthermore, users may treat CMC as an experimental environment and thus “play” with their identity and try out different personalities (Turkle, 1995).

Some studies have been carried out to compare the nature of friendship in conventional CMC and offline communication. Wellman and Gulia (1999) for instance found that people have a higher number of online friends because it is easier to make friends online than offline. However, the quality of the relationship is weaker in an online setting. Although Walther (1995) contended that it is possible to develop strong online friendship, it takes longer than in offline communication.

**3D CMC and Virtual World**

Conventional CMC technologies are mainly text-based (Pfeil, 2007). Although the fundamental technology of CMC has not changed in the last decade (Preece & Maloney-Krichmar, 2003), the way of using it for human-human communication has evolved considerably, from e-mail and synchronous chatting to online forum, blogs and Wikis.

New technologies such as 3D Virtual spaces, such as MMORPGs and Second Life (Linden Lab, 2003) offer a much richer form of social interactions where users can not only communicate through text-based chat, but also interact with each other through virtual artefacts. Furthermore, these technologies not only mediate social interaction, but also support group formation, which leads to community building. As such, user interaction is considerably more complicated than the conventional CMC tool.

These 3D worlds often feature a large number of virtual locations users can visit and a variety of virtual artefacts users can use to interact with, with each other. In some cases, they can even construct
new artefacts and locations utilising simple modelling tools and scripting languages. Whilst some 3D virtual worlds are designed with game-like goal structures that impose obstacles or challenges, some are completely open, meaning that the users are free to do as they please.

Although sociability issues of conventional CMC are well studied and documented, we have very little understanding on social interactions in 3D CMC. Therefore, it is worth investigating user activities in such environments in order to cast some light on the group formation process and other sociability issues.

It might be potentially more challenging in researching this 3D CMC, in which communication takes place both through texts and other “virtual actions” users can perform with their 3D avatars. Unlike the avatar in conventional CMC which is often a static graphical or animated representation of the user, in 3D CMC, the avatar can interact with other avatars directly in the virtual space. A 3D avatar can perform a wide range of actions on the 3D world and other avatars. For instance, it is not uncommon that avatars can hug, kiss or wave to each other. There is also research on the facial expression of 3D avatars (Clarkson et al., 2001), implemented in the 3D CMC context with the intention to enhance non-verbal communication. Moreover, given the fantasy theme of some 3D CMC environments, new sets of rules for virtual communication which are completely different from physical communication might arise. This is worth investigating as well as groups open operate within the boundary of norms and rules that emerge through user interaction.

**Ubiquitous Computing**

Another exciting future trend in HCI is the emergence of ubiquitous computing, in which information processing is thoroughly diffused into objects and experiences of everyday life. In another word, computers are disappearing. Users are no longer consciously engaged in using the computers. Instead they are operating these devices which are so well integrated into artifacts of everyday activities without being aware of using the computers.

Perhaps the most obvious example is the mobile phone, and indeed mobile computing has witnessed an explosion of research interest within and beyond HCI community.

Other less obvious examples could include computerized refrigerators which are able to detect their contents, plan and recommend a variety of recipes, automatically shop according to the users’ needs.

The focus of ubiquitous computing from the point of view of HCI suggests a shift from tool-focused design to activity-focused design. The primary objective is thus to design tools which can be seamlessly mediate everyday activities without interfering with users’ tasks. One such area is wearable computing which has the potential to support human cognitions, facilitate creativity and communication. Unlike mobile devices, wearable computers are attached to human, thus reducing the possibility of interruption or displacement.

**Novel Interaction Techniques**

With the integration of the computers into everyday life, there is a call for new interaction techniques as keyboards and mice are no longer sufficient as input devices.

Techniques such as natural language processing (NLP), a sub area of artificial intelligent, have been incorporated into the design of computer devices to recognize speeches, thus making interaction more intuitive. This automatic speech recognition can not only convert spoken words into machine readable strings, but also recognize and identify the person who speaks. Already, it has some impacts on our everyday life particularly on disable people who suffer from motor control impairment.
Perhaps a more ambitious application of NLP is to go beyond text-speech or speech-text conversion to actually understand human natural language. The research goal in this area is to develop a machine that can engage in meaningful conversation with human. Although still in its infancy, it is certainly a promising area which will benefit HCI greatly.

Another interesting interaction mode is what is known as haptic interaction which draws largely from the infamous interaction style in HCI, direct manipulation. The idea is to provide the users with greater freedom of manipulation that includes touch and feel. This technique aims to effectively bridge the gap between tangible interfaces and virtual/intangible representations. One example is the augmentation of everyday objects in which digital data is superimposed on physical objects which can be used to manipulate the digital data.

Recent development has also begun to utilize other parts of our body for interaction. Eye tracking for instance, which has been used extensively in research in psychology, cognitive linguistic and other areas, has been adopted in HCI research to study usability of Web sites and other software. Recently, its use in HCI has expanded to be applied as an interaction technique. Eye tracking system is now being used especially for the disabled to surf the Web, e-mail, and so forth with eye movements.

**Accessibility and Universal Design**

Finally we believe that Endeavour in designing assessable technology will continue to be a main focus in HCI. One major accessibility research is the Web design since the Web has rapidly become more and more pervasive in almost everybody’s lives.

The challenge lies in the creation of resources that can be used by the widest spectrum of potential visitors rather than an idealized “average,” there is a need to consider universality of Web delivery.

The idea accessibility has gone beyond the basic concept of “designing for disability” to universal design, allowing access by everyone.

This requires consideration of the needs and requirements of individuals with disabilities, older persons, people for whom English is a second language, people whose cultures and backgrounds are dissimilar to those of Web developers, and those using outdated hardware and software, to name a few.

For that reason, the key objective of this research direction is to look at various aspects of universal Web design and evaluation in a new perspective by focusing on the user aspect of universal Web design and interaction and to present the wide range of advanced technology that can help disadvantaged users get access to Web information.

The same idea also applies to software design. For instance, child-computer interaction has emerged as a sub-field of HCI that deals with designing particularly multimedia learning software for children. Other active areas of research include web design for elderly people, gender differences, cultural issues, and so forth.

All these efforts in accessibility design no longer contribute to the development of ease-of-use applications for specific user groups, but also improve interaction experiences for mainstream users in general.

About the Editor

Panayiotis Zaphiris is a reader in human-computer interaction at the Centre for HCI Design. He got his B.Sc and M.Sc. from the University of Maryland College Park (USA). Panayiotis got his PhD (in human-computer interaction) from Wayne State University where he was also a research assistant at the Institute of Gerontology. Panayiotis’ research interests lie in HCI with an emphasis on inclusive design and social aspects of computing. He is also interested in Internet related research (Web usability, mathematical modelling of browsing behaviour in hierarchical online information systems, online communities, e-learning, Web based digital libraries and finally social network analysis of online human-to-human interactions). He has authored over 110 papers and four books in this area including a recently released book titled User-Centered Design of Online Learning Communities (Lambropoulos and Zaphiris, 2006). He is principal investigator for the AW-Model EPSRC/BBSRC project funded under the SPARC scheme. Panayiotis was the principal investigator on the JISC-funded “Usability Studies for JISC Services and Information Environment” and “Information Visualisation Foundation Study” projects which looked at usability and information visualisation in the context of online learning environments. Finally, he was the co-principal investigator on the largest ever conducted Web accessibility study (the DRC funded “An in-depth study of the current state of Web accessibility” project) that assessed at the accessibility of 1000 UK Web sites. More information about Panayiotis’ research can be found at: http://www.zaphiris.org

Chee Siang Ang is a research fellow in the Centre for Human-Computer Interaction (HCI) Design. He is interested in human interactions and social tendencies in the virtual world, particularly Second Life, from a sociological, psychological and HCI perspective. His main research interests include the psychology and sociology of computer games, virtual worlds or 3D Computer-Mediated Communication (CMC), learning theories particularly in gaming, digital media such as interactive narrative and simulation.
This section serves as the foundation for this exhaustive reference tool by addressing crucial theories essential to the understanding of human-computer interaction. Chapters found within these pages provide an excellent framework in which to position human-computer interaction within the field of information science and technology. Individual contributions provide overviews of ubiquitous computing, cognitive informatics, and sociotechnical theory, while also exploring critical stumbling blocks of this field. Within this introductory section, the reader can learn and choose from a compendium of expert research on the elemental theories underscoring the research and application of human-computer interaction.
Chapter 1.1
Introduction to Ubiquitous Computing

A BRIEF HISTORY OF UBIQUITOUS COMPUTING

Mark Weiser

The term ubiquitous computing was coined and introduced by the late Mark Weiser (1952-1999). He worked at the Xerox Palo Alto Research Center (PARC, now an independent organization). PARC was more or less the birthplace of many developments that marked the PC era, such as the mouse, windows-based user interfaces, and the desktop metaphor (note that Xerox STAR preceded the Apple Lisa, which again preceded Microsoft Windows), laser printers, many concepts of computer supported cooperative work (CSCW) and media spaces, and much more. This success is contributed (among other reasons) to the fact that PARC managed to integrate technology research and humanities research (computer science and “human factors” in particular) in a truly interdisciplinary way. This is important to bear in mind since a considerable number of publications argue that the difference between UC and Ambient Intelligence was the more technology/networks-centered focus of the former and the more interdisciplinary nature of the latter that considered human and societal factors. We do not agree with this argument, in particular due to the nature of the original UC research at PARC—and the fact that quite a number of UC research labs worldwide try to follow the PARC mindset. Indeed, Mark Weiser concentrated so much on user aspects that quite a number of his first prototypes were mere mockups: during corresponding user studies, users had to imagine the technology side of the devices investigated and focus on use cases, ideal form factors and desired features, integration into a pretend intelligent environment, and so forth.
Weiser’s Vision of UC

Maybe the most frequently cited quotation from this article reads as follows: “The most profound technologies are those that disappear. They weave themselves into the fabric of everyday life until they are indistinguishable from it.” This was Mark’s vision for the final step in a development away from “standard PCs”, towards a proliferation and diversification of interconnected computer-based devices. A deeper understanding of Mark Weiser’s visions can be drawn from his position towards three dominant, maybe overhyped trends in computer science at his time: virtual reality, artificial intelligence, and user agents. With a good sense for how to raise public attention, Mark criticized these three trends as leading in the wrong direction and positioned UC as a kind of “opposite trend”. We will follow Mark’s arguments for a short while and take a less dramatic view afterwards.

UC vs. Virtual Reality (VR)

According to Mark, VR “brings the world into the computer”, whereas UC “brings the computer into the world”. What he meant was that VR technology is generally based on elaborate models of an existing or imagined (excerpt of the) world. This model contains not only 3D (geometric) aspects but many more static and dynamic descriptions of what is modeled. For instance, digital mockups of cars have been pushed to the point of simulating crash tests based on the car /obstacle geometry, static, and dynamic material characteristics, laws of physics, and so forth. As the sophistication of models grows, more and more aspects of the world are entered into the computer, finally almost everything happens in the virtual space and even the human becomes a peripheral device for the computer, attached via data gloves and head-mounted displays. Mark Weiser criticized mainly the central and peripheral roles of computers and humans, respectively. He proposed to follow the UC vision in order to *invert* these roles: by abandoning the central role of computers and by embedding them in the environment (in physical objects, in particular), room is made for the human in the center. In this context, he used the term “embodied virtuality” as a synonym for UC. The cartoons in Figure 1 were made by Mark Weiser and provided by courtesy of PARC, the Palo Alto Research Center, Inc.

UC vs. Artificial Intelligence (AI)

In essence, Mark Weiser criticized the overly high expectations associated with AI in the 1980’s. In the late 1980’s and early 1990’s, that is, at the time when he developed his UC vision, AI research had to undergo a serious confidence crisis. The term AI had not been associated with a commonly accepted, reasonably realistic definition, so that the association with human intelligence (or the human brain) was destined to lead to disappointments. The AI hype had provided researchers with considerable funds—but only for a while. Mark Weiser proposed to take a different approach towards a higher level of sophistication of computer-based solutions (which had been the goal of AI at large). He considered it a more reasonable objective to concentrate on small subsets of “intelligent behavior” and to dedicate each computer to such a subset. Higher sophistication would be fostered by interconnecting the special-purpose computers and by making them cooperate. This reasoning lead to the term *smart*, considered more modest than the term *intelligent*. Sensor technology plays an important role in dedicating computers to a small subset of “understanding the world around us” (a key element of intelligent behavior). By widely deploying and interconnect-
ing sensor-based tiny computers, one would be able to integrate environmental data (location, temperature, lighting, movement, etc.) and use this information to produce smart behavior of computers and computerized physical objects.

**UC vs. User Agents (UA)**

In contrast to virtual reality and artificial intelligence, the term *user agent* is not very prominent in the general public. At the time referred to, UAs were thought as intelligent intermediaries between the user and the computer world, that is, as an approach towards increased ease-of-use or better human-computer interaction. User agents were often compared to the common perception of British butlers who are very discreet and unobtrusive, but always at disposal and extremely knowledgeable about the wishes and habits of their employers. Following this analogy, UAs were installed as autonomous software components between applications and users, inspecting and learning from the user-software application. Mark Weiser challenged five requirements usually derived from this analogy for user agents and proposed UA as a better alternative for the first three; as to the last two, he judged the necessary base technology as immature:

1. UAs were supposed to give advice to their users based on what they had learned. Mark Weiser asked, in essence, why they would not do the job themselves—a promise that UC should fulfill;
2. UAs were supposed to obey the user, for example, by applying planning algorithms to basic operations with the aim to fulfill the goals set by a user. In contrast to this approach, UC was intended to behave rather proactively, that is, to propose and even act in advance as opposed to reacting on command;
3. A third widespread requirement suggested that UAs should intercept the user-application interface. UC in contrast should be more radical and take over the interaction or carry out functions on its own—an approach presumed by Mark Weiser to be the only viable one if humans were to be surrounded by hundreds of computers;
4. A basic assumption about UAs was that they would listen to the (interactions of) the user. Mark Weiser considered natural language processing technology and speech recognition technology at his time to be far too immature to promise satisfying results in this respect;
5. UAs should learn the users’ preferences, wishes, and so forth by observation. Again, the necessary (machine learning) technology was judged to be too immature to live up to this promise.

![Figure 1. Mark Weiser’s cartoons about UC vs. virtual reality](image-url)
We will resume the VR / AI / UA discussion in the next large section.

Mark Weiser’s Three Key Devices

We want to finish this lengthy but still extremely compressed, much simplifying and abstracting treatment of Mark Weiser’s contributions by looking at three devices. These complementary UC devices were prototyped at his lab; investigated in the context of PARC’s typical creative, team-oriented setting, all three were thought as electronic replacements for the common “analog” information appliances.

The Xerox “Pad” can be considered to be the prototype and father of present PDA’s, introduced even before Apple’s Newton appeared in 1993. The initial concept was that of an electronic equivalent to “inch-size” information bearers, namely “PostIt Notes”: easy to create and to stick almost everywhere, available in large quantities. As the PDA analogy suggests, the prototypes had a lot more functionality than PostIt Notes—but were also a lot more expensive and cumbersome to handle by design (not only due to short and mid-term technology limitations).

The Xerox “Tab” can be considered to be the prototype and father of present Tablet PC’s. The analogy from the traditional world was that of a “foot-size” information bearer, namely a notebook or notepad. One may infer from the rather stalling market penetration of Tablet PC’s that technology is still not ready for mass market “Tabs” today, but one may also expect to find a pen centric, foot size, handheld computer to become very successful any time soon. An interesting facet of the original Tab concept was the idea that Tabs would in the future lay around for free use pretty much as one finds paper notebooks today, for example, as part of the complementary stationery offered to meeting participants.

The Xerox “Liveboard” was the prototype of present electronic whiteboards. A PARC spinoff company designed and marketed such boards, and today many companies like Calgary-based SmartTechnologies Inc. still sell such devices. Liveboards represented the “yard-size” information bearers in the family of cooperating devices for cooperating people. In contrast to many devices sold today, Liveboards supported multi-user input pretty early on.

The developments and studies conducted at Mark Weiser’s lab emphasized the combination of the three device types for computer supported cooperation, and cooperative knowledge work in particular.

While Mark Weiser was a truly outstanding visionary person with respect to predicting the future of hardware, that is, UC nodes (proliferation of worn and embedded networked devices, specialized instead of personal general-purpose computers, numbers by far exceeding the number of human users), two other people were more instrumental in generating awareness for the two remaining big challenges mentioned in the preface of this book, namely integrative cooperation and humane computing; the former of these challenges was emphasized by Kevin Kelly, the latter by Don Norman. A deeper analysis reveals that for the second aspect, humane computing, it is very difficult to argue about the true protagonists. Readers remember that Mark Weiser was actually placing a lot of emphasis on usability, by virtue of his education and mindset and in the context of the human focus of PARC. He also coined the exaggerated term “invisible” for mature technology. On the other hand, Don Norman was not advocating the humane computing challenge in all its facets yet. Nevertheless, we want to highlight him next as maybe the single most important advocate of this challenge.

The Book Out of Control by Kevin Kelly

In 1994, K. Kelly published a book entitled Out of Control. The thoughts expressed by Kelly were an excellent complement to Mark Weiser’s
publications. While the latter emphasized the emergence of networked small “neuron like” (i.e., smart) UC nodes, Kelly emphasized the integrated whole that these neurons should form. His starting argument was the substantiated observation that the complexity of the made, that is, of human-made systems or technology, approached the complexity of the born, that is, of “nature-made” systems, such as human or biological organisms, human or biological societies (cf. ant colonies), and so forth.

This observation led to the obvious requirement to investigate the intrinsic principles and mechanisms of how the born organized, evolved, and so forth. By properly adopting these principles to “the made”, this complexity might be coped with. Research about the organization and evolution of the born should be particularly concerned with questions such as: how do they cope with errors, with change, with control, with goals, and so forth. For instance, beehives were found not to follow a controlling head (the queen bee does not fulfill this function), and it is often very difficult to discern primary from subordinate goals and to find out how goals of the whole are realized as goals of the individuals in a totally decentralized setting.

Kevin Kelly summarizes central findings and laws of nature several times with different foci. Therefore, it is not possible to list and discuss these partly conflicting findings here in detail. An incomplete list of perceived central laws “of God” reads as follows: (1) give away control: make individuals autonomous, endow them with responsible behavior as parts of the whole, (2) accept errors, even “build it in” as an essential means for selection and constant adaptation and optimization, (3) distribute control truly; that is, try to live with no central instance at all, (4) promote chunks of different kinds (e.g., hierarchies) for taming complexity, and (5) accept heterogeneity and disequilibrium as sound bases for survival.

The Book The Invisible Computer by Donald Norman

Don Norman emphasized the “humane computing” grand challenge described in the preface of this book. World renowned as an expert on usability and user-centered design, he published The Invisible Computer in 1999. He considered the usability problems of PC’s to be intrinsically related to their general-purpose nature and thus perceived the dawning UC era more as a chance than a risk for humane computing. The intrinsic usability problems that he attributed to PCs were rooted in two main anomalies, according to Don Norman: (1) PCs try to be all-purpose and all-user devices—a fact that makes them overly complex, and (2) PC’s are isolated and separated from daily work and life; truly intuitive use—in the context of known daily tasks—is therefore hardly possible. From this analysis, Norman derived various design guidelines, patterns, and methodological implications, which we will summarize again at an extremely coarse level:

1. He advocated UC nodes using the term “information appliances”: dedicated to a specific task or problem, they can be far simpler and more optimized;
2. He further advocated user-centered development: especially with a specific user group in mind, “information appliances” as described previously can be further tailored to optimally support their users;
3. Norman stated three key axioms, that is, basic goals to be pursued during design and development: simplicity (a drastic contrast to the epidemic “featurism” of PC software), versatility, and pleasurability as an often forgotten yet success critical factor;
4. As a cross-reference to the second big UC challenge (integrative cooperation), he advocated “families of appliances” that can be easily and very flexibly composed into systems.
History Revised

The preceding paragraphs are important to know for a deeper understanding of the mindset and roots of UC. However, about 15 years after the time when the corresponding arguments were exchanged, it is important to review them critically in the light of what has happened since. We will first revise the three “religious disputes” that Mark Weiser conducted against AI, VR, and UAs. To put the bottom line first, the word “versus” should rather be replaced by “and” today, meaning that the scientific disciplines mentioned should be (and have, mostly) reconciled:

As to UC and VR, specialized nodes in a global UC network can only contribute to a meaningful holistic purpose if models exist that help to cooperatively process the many specialist purposes of the UC nodes. In other words, we need the computer embedded into the world and the world embedded in the computer. Real Time Enterprises are a good example for very complex models—in this case, of enterprises—for which the large-scale deployment of UC technology provides online connectivity to the computers embedded into the world, that is, specialized nodes (appliances, smart labels, etc.). In this case, the complex models are usually not considered VR models, but they play the same role as VR models in Mark Weiser’s arguments. The progress made in the area of augmented reality is another excellent example of the benefit of reconciliation between UC and VR: in corresponding applications, real-world vision and virtual (graphical) worlds are tightly synchronized and overlaid.

As to UC and AI, Mark Weiser had not addressed the issue of how interconnected, smart, that is, “modest”, specialized nodes would be integrated into a sophisticated holistic solution. If the difference between AI and the functionality of a single smart UC node (e.g., temperature sensor) was comparable to the difference between a brain and a few neurons, then how can the equivalent of the transition (evolution) from five pounds of neurons to a well-functioning brain be achieved? Mark Weiser did not have a good answer to that question—such an answer would have “sounded like AI” anyway.

Today, there is still not a simple answer yet. The most sophisticated computer science technology is needed in order to meet the integration challenge of how to make a meaningful whole out of the interconnected UC nodes. However, the state of the art has advanced a lot and our understanding for what can be achieved and what not (in short term) has improved. For instance, socionic and bionic approaches have become recognized research areas. A mature set of methods and algorithms is taught in typical “Introduction to AI” classes today and has replaced the ill-defined, fuzzy former understanding of the area. Thus the boundaries between AI and computer science are more blurred than ever and their discussion is left to the public and press.

As to UC and UAs, remember that Mark Weiser considered UAs as “too little” in terms of what they attempted (at least too little for the UC world envisioned by him), yet “too much” in terms of what the underlying technology was able to provide. This left doubts about how the even more ambitious goals of UC could be met, namely active (proactive, autonomous, even responsible) rather than reactive (obeying) behavior. In other words, Mark Weiser was right when he advocated active as opposed to reactive behavior, but he had little to offer for getting there. Luckily, the technologies that he had then considered immature (e.g., speech processing, NLP, machine learning) have advanced a lot since.

All in all, Mark Weiser’s arguments from 15 years ago (1) provide a deep understanding of the field, (2) should be modified towards a more conciliatory attitude (in particular with respect to AI and VR / complex “world models”), and (3) have become more substantiated in certain respects since technology advancements make some of his more audacious assumptions more realistic (but most visions of his “opponents”, too). In other
words, Mark Weiser’s visions were and still are marking the research and developments made by the UC community. His concepts and predictions were accurate to a degree that was hardly paralleled by any other visionary person. Restrictions apply as to his overly drastic opposition to VR, AI, and UAs: some of the exaggerated promises of these were repeated by him in the UC context - right when he denounced the over-expectations raised by AI and UAs! VR and AI in particular should be reconciled with UC. Maybe Weiser underestimated the two grand challenges of the UC era, namely “integrative cooperation” and “humane computing”.

Kevin Kelly and Donald Norman emphasized these two challenges, respectively. Looking at the advancements in totally decentralized systems, Kelly’s promises can be evaluated as too extreme today: bionics social science inspired, and autonomous (or autonomous) computing have advanced a lot. However, two restrictions still apply: (1) less decentralized systems still prove to be extremely viable in daily operation—it will be hard for fully decentralized systems to really prove their superiority in practice; (2) system-wide goals must still be planned by some centralized authority and—to a certain extent manually—translated into methods for fully decentralized goal pursuit; evolution-like approaches that would generate optimization rules and their pursuit automatically in a fully decentralized systems are still hardly viable. As a consequence, the present book will not only describe the above-mentioned computing approaches in part “Scalability”, but also other aspects of scalability.

As to Don Norman, he was right to advocate simplicity as a primary and key challenge. However, he maybe underestimated the ‘humane computing’ problems associated with the nomadic characteristics and ‘integrative cooperation’ challenge of the UC era. The usability of the integrated whole that we advocate to build out of UC nodes is by far not automatically endowed with easy-to-use user interaction just because the participating appliances exhibit a high degree of usability. On the other hand, only the integration that is, federation of miniature appliances with large interaction devices (wall displays, room surround sound, etc.) may be able to provide the usability desired for an individual device.

As we conclude this section, we should not forget to mention that the UC era was of course not only marked by just three visionary people.

**TERMS AND SELECTED STANDARDS**

While there is a lot of agreement among researchers and practitioners worldwide that the third era of computing is dawning as the era of networked, worn/portable and embedded computers, there is not so much agreement about what to call that era. This fact is something of an obstacle, for instance for wider recognition in politics (the crowd does not scream the same name as one may put it). This situation is aggravated by the fact that partial issues and aspects of Ubiquitous Computing are also suffering from buzzword inflation. With this background in mind, one may understand why we list a considerable number of these buzzwords below and provide a short explanation, rather than swapping this issue out into a glossary alone. Knowledge of the following terms is indeed necessary for attaining a decent level of “UC literacy”.

**Synonyms for Ubiquitous Computing**

First, we want to look at the terms that describe—more or less—the third era of computing as introduced:

- **Post-PC era**: The root of this term is obvious, it describes ‘the era that comes after the second, that is, the PC era. We suggest avoiding this term since it points at what it
Pervasive computing: A distinction between the word ubiquitous and pervasive is difficult if not artificial. One could argue that the term pervasive eludes more to the process of penetration (i.e., to the verb pervade) whereas ubiquitous eludes more to the final state of this process. We suggest that pervasive computing and ubiquitous computing are synonyms, one (pervasive) being slightly more common in industry (its origin has been attributed to IBM), the other one (UC) being slightly more common in academia.

Ubiquitous computing: The term may be interpreted as “computers everywhere”. We are using it as the notion for the third era of computing throughout the book and prefer it, among others, because we try to fight buzzword mania and dislike the invention of additional terms for a named concept. We therefore propose to stick to the first (reasonable) term invented and somewhat broadly accepted; since Mark Weiser is the first visionary person who sketched essential characteristics of the dawning era and since he invented the term UC, the question of what is the oldest well-known term should not be questionable.

Ambient intelligence: This term was invented in particular in the context of the European Union’s research framework programs (5, 6, 7). As a positive argument, one may say that the two words reflect the grand challenges of UC as stated in this book: ambient may be associated with the challenge of humane computing, making UC systems an integral part of our daily life. Intelligence may be interpreted as the challenge of integrative cooperation of the whole that consists of myriads of interconnected UC nodes. On the downside, one should remember that Mark Weiser had intentionally avoided the term “intelligence” due to the over-expectations that AI had raised. We suggest avoiding this term, too, because it is still burdened with these over-expectations and because it is still ill defined.

Disappearing / invisible / calm computing: All three terms are less common than UC and pervasive computing. Their roots have been discussed in the historical context above. Obviously, disappearing describes again a process while “invisible” describes a final state. “Calm” emphasizes hearing as opposed to vision like the other two. In any case, the terms “invisible” and “disappearing” are not very well chosen (despite our tribute to Don Norman) since computers and interfaces that have totally disappeared cannot be commanded or controlled by humans any more. Since we doubt that 100% satisfactory service to the user can be paid at all without leaving the customer, that is the user, the option to explicitly influence the service behavior, we consider the term misleading. We favor again Mark Weiser’s notion of computers that are so well interwoven with the fabric of our lives that we hardly notice them.

Mixed-mode systems: This is a term used to describe the heterogeneity of UC nodes, in contrast to the rather resource rich, general purpose PC’s of the last era. This term is even less common, but pops up every now and then like those previously discussed, and should not be used to describe UC as a whole since it emphasizes a particular aspect.

Tangible bits: This term has found some currency in the Netherlands and Japan, but remained rather uncommon in general. It refers mainly to the fact that networked computers are becoming part of the physical world.

Real time enterprise: This term has been explained in the preface of the book and is not
thought as a synonym for UC, but rather as a very important and cutting-edge application domain that may drive down the learning curve, that is, prices of UC hardware and solutions.

It was mentioned in the preface that some authors argued in favor of one or the other of the UC synonyms, saying that their choice was more far-reaching in time (the other ones being intermediate steps) or space (the other ones only comprising a subset of the relevant issues). However, we cannot follow these arguments, mainly because research labs and projects around the world work on the same subjects, some more advanced or holistic, some less ambitious or more specialized, carrying the names UC, pervasive computing, and ambient intelligence rather randomly.

Towards a Taxonomy of UC Nodes

Throughout this book, UC nodes will be categorized according to different aspects. In the context of reference architectures further below, we will emphasize the role of UC nodes in a holistic picture. In the present paragraph, we want to try categorizing them as devices. It should be noted that in the preface of the book, we already provided a preliminary, light weight introduction. The difference between carried (worn, portable) and encountered nodes was emphasized and four preliminary categories (wearables, sensors, appliances, and smart labels) were briefly described. It soon became clear that smart labels attached to goods must be distinguished again from those attached to humans, although the base technology may be the same.

In a second, more serious attempt to categorize UC nodes as device categories, we propose the following distinction (see Figure 2):

1. Devices attached to humans
   a. Devices carried: Here we further distinguish three subcategories: (1) mobile devices, synonymous with portable devices, contain rather general purpose computers and range from laptops via PDA’s to mobile phones and the like, (2) smart badges, that is, smart labels serve for identification, authentication and authorization of humans and possibly further purposes, and (3) body sensors of all kinds play an increasingly important role in particular in the fitness and health context;
   b. Devices worn: These wearables range from truly sophisticated, computer-augmented cloths and accessories to prototypes that are built from standard components (PDA in a holster with headset, etc.). A further categorization is not attempted since the spectrum is rather blurred;
   c. Devices implanted: while there is a lot of hype about implanted RFID tags and networked health implants, the many issues (e.g., health, privacy, or dependability) around the necessary device-environment communication have not permitted this category to become widespread.

2. Devices encountered
   a. Smart items denote computer-augmented physical objects. The terms “smart object” and “smart product” are used with subtle differences depending on the context to denote more sophisticated variants of smart items, such as smart items that proactively communicate with the users. We suggest treating smart items as the most general term and to distinguish the following subcategories: (1) smart tags as the least sophisticated variant: they can be considered to be mimicry for embedded computers: by attaching a smart tag to a physical object, a physically remote computer (often
in proximity, though) can take over some of the functionality that would be embedded otherwise. This approach opens the door for turning even the cheapest products into UC nodes. The term “smart label” is sometimes used synonymously; sometimes it is used as the comprehensive term for smart tags and smart badges (attached to humans, see earlier discussion). We suggest sticking to the term smart tag for the smart item sub-category described here; (2) networked sensor nodes, and (3) networked appliances denote the other subcategories of smart items. They were already introduced in the preface of this book.

b. **Smart environments** denote the surroundings of smart items, that is, the additional communication and compute power installed in order to turn an assembly of smart items into a local, meaningful whole.

The reader must be aware that all terms arranged in the taxonomy are not settled yet for a common understanding. For instance, one might argue whether a sensor network that computes context information for networked appliances and users should be considered a set of smart items (as we defined it) or a part of the smart environment. Nevertheless, we find it useful to associate a well-defined meaning with these terms and to apply it throughout the book (see Figure 2).

In addition, it should be noted that **smart environments** (with integrated smart items) constitute a particularly important research area—maybe because they permit researchers and project leaders to implement self-contained “little UC worlds” without a need for multiparty agreements about interoperability standards. In particular, “smart homes” were among the first subjects of investigation in the young history of UC. Prestigious projects in the smart home area were and are conducted by industry (Microsoft eHome, Philips AmbientIntelligence initiative, etc.) and academia (GeorgiaTech AwareHome, MIT House, etc.). HP made an early attempt to overcome the isolation of such incompatible islands by emphasizing standard middleware in the Cooltown project). Quite a number of projects about smart homes terminated without exciting results, not to the least due to insufficient business impact (note our argument in favor of Real Time Enterprises as a more promising subject). More recently, smart homes projects have focused on issues considered to be particularly promising, as was discussed in the preface to this book. Important areas comprise home security, energy conservation, home entertainment, and particu-
larly assisted living for the aging society—a topic considered particularly interesting in Europe (1 year prolongation of independent living saving about half a billion Euros in Germany alone). Renowned large-scale projects were carried out, for example, in Zwijndrecht (Belgium) and Tønsberg (Norway) in this respect.

A Few More Relevant Terms

A few more UC terms—and sometimes, corresponding concepts—are worth mentioning.

- **Smart dust** is a term used for sensor networks if the emphasis is on miniaturization and the concept is based on one-time deployment and zero maintenance. Environment data sensors are often cited as an example, the vision then is to deploy them, for instance, from an aircraft, and let them monitor the environment until they fail. Environment-friendly degradation is a major issue here, of course.

- **Things that think** was the name of an early UC project led by Nicholas Negroponte at the MIT media lab. Other authors have since hijacked the term.

- **Smart paper** denotes the vision of a display device that would exhibit characteristics comparable to traditional paper in terms of weight, robustness, readability, and so forth, and loadable with the content of newspapers, journals, books and so forth. It would help to save paper and revolutionize the press distribution channels and more. Many projects that were not even close to this vision had, and continue to have, the name “smart paper”.

- **Smart wallpaper** is a similar term to smart paper in that it extrapolates the above mentioned characteristics to wall-size devices.

- **Smart <you-name-it>:** virtually every noun has been associated with the attribute smart recently, not always alluding to the characteristics of UC nodes. For instance, smart materials are supposed to adapt to the context of use, with no IT involved. Most of the time though, smart <something> alludes to a physical object that has been augmented with an embedded computer.

- **The Internet of things** is a term favored by the press. It is not considered appropriate as a term for UC as a whole by the authors since it emphasizes the hardware side of UC as opposed to the human side, which was already described as crucial and as a major challenge (cf. humane computing). Most publications that favor this term concentrate on the two standards discussed in the following section.

The EPCglobal Standard

As mentioned at the beginning, we will only sketch two important standards in the UC context. Other standards are too unimportant, too immature, too specific (they might be treated in one of the focused parts of this book), or part of the background knowledge about well-established technology that this book cannot cover. The first standard to mention is EPCglobal and was mentioned in the preface of this book. As mentioned, it is meant to succeed the barcodes that encode the European article number or universal product code on current consumer products. The 96-bit Electronic Product Code EPC is usually stored on RFIDs (a subcategory of smart tags, as we can now say) and can be read:

- From a greater distance (e.g., 10m)
- With better reading accuracy
- With much less effort (e.g., en-passant by a RFID reader gate as opposed to carefully with line-of-sight connection by a barcode scanner)
- In bulk (RFID readers can read, for example, a hundred tags at once)
Since the EPC contains a 36-bit serial number, individual items can be tracked and traced. For instance, theft can be much more easily attributed to criminals, product life cycles can be recorded more accurately, product lots with manufacturing errors can be called back more specifically, etc. On the other hand, the serial number may in principle be used to trace an individual, too, if she carries around an RFID tagged product. This privacy issue has raised many concerns in recent years and amplified the decision of the whole sales and retail industry to focus on tagging their containers, palettes, cases, etc., for a start. So-called item level tagging is only envisioned for highly valuable goods initially; it may enter the mass market when tag prices and system costs have come down and after settling the privacy issues.

Figure 3 depicts the functioning of EPC smart tags in an overall IT infrastructure. In step 1, an EPC code is read from a product. In the example, each carton on the palette could contain a number of tagged products. The residual example would then explain the action for just one such tag. Usually prior to reading the tag, the system has already searched and discovered servers capable of ‘resolving’ certain ranges of EPC code. Based on the results of this discovery process, the appropriate ‘resolution node’, called an ONS server, is asked to resolve the EPC code, that is to translate it into a global Internet address where the relevant product information is actually stored. The product information is encoded in a standardized way, using the so-called product markup language PML, an XML derivate.

The second generation of RFID tags introduced in 2006 features improved bulk reading (hundreds of tags simultaneously), size and cost improvements. “Printable” tags have become common: these paper labels with embedded RFID chips can be custom imprinted with custom human-readable information. The chips themselves are not altered in the printer and they come with pre-assigned EPC codes from the manufacturer.

The OSGi Standard

The Open Services Gateway Initiative (OSGi) is an industry driven nonprofit consortium. OSGi standardized a Java virtual machine (JVM). This JVM can be considered a standardized virtual ‘computer’ that runs on any real computer and is capable of executing programs that are transmitted to it, so-called bundles. OSGi standardizes not only the format for bundles, but also the necessary protocols and procedures for authenticating and authorizing senders of bundles, for replacing and updating bundles (remote maintenance), for discovering other bundles, and so forth. OSGi
bundles are particularly useful for controlling the functionality of networked appliances. Possible use cases include SetTopBoxes, Vehicles (note that car electronics today requires much shorter maintenance cycles than the mechanical parts, especially for software updates!), consumer electronics, and so forth. As to smart homes, the favored concept is that of a residential gateway that is connected to the global Internet and receives updates for smart home appliances via OSGi. The residential gateway may then forward bundle updates and so forth to the relevant appliances if needed.

OSGi has a number of deficiencies. For instance, it is not considered to be very resource effective. Nevertheless, it has tremendous impact as a de facto standard for dealing with some of the elementary aspects of coping with global UC systems in a platform and vendor independent way.

REFERENCE ARCHITECTURES FOR UBIQUITOUS COMPUTING

The Importance and Role of a Reference Architecture

A sophisticated distributed infrastructure is needed in order to make a myriad of networked UC nodes communicate and cooperate. If interoperability is to take on a worldwide scale, means for agreement among arbitrary participants must be provided. Ideally, the move from isolated proprietary UC solutions to a world of cooperating UC components is driven by so-called reference architectures which establish several levels of agreement: on level one, a common terminology and conceptualization of UC systems is established in order for researchers and practitioners to speak the same language and to work on the same global UC vision. On the second level, a common understanding of the ensemble and components of a typical UC system is established, including the potential roles of the components. On level three, basic functional principles can then be agreed upon. A fourth level is desirable but beyond the scope of reference architectures, that is concrete standards for intercomponent cooperation. This level is discussed in the introduction to the part Scalability.

Reference Architectures in a More Realistic World

In reality, a worldwide common understanding and corresponding standards have to be developed in a struggle for the best solution. Real life has a large impact on what becomes widespread. By “real life” we mean breaking research results, industry practice, experiences gained with proprietary prototypes and realizations, user acceptance, and not least business interests defended by global industrial players. Nevertheless, the exercise of proposing and refining reference architectures—in communication with the stakeholders mentioned—plays a key role in a struggle for globally interoperable solutions. Here reference architectures must be invented and published and then consolidated and reiterated based on feedback by the stakeholders.

Prominent Examples from the Past

The ISO reference architecture for open systems interconnection (OSI) was developed in the 1970s as an important step towards global networks. OSI was very successful in that it led to a common terminology and a common understanding of the components of computer networks including their roles. The fourth level aforementioned above: ISO standards for communication protocol, were not nearly as successful as the reference architecture itself. Rather, the Internet protocols TCP and IP took over almost the entire market. Nevertheless, the OSI reference architecture was extremely influential on the computer networking community as a whole and on the Internet in particular.
Another ISO reference architecture is ODP (open distributed processing). It emphasizes complex distributed systems and applications. An influential contribution of ODP is its support for different viewpoints of various stakeholders. In particular, ODP emphasized the importance of enterprise modeling for application development. All too often, applications are modeled and built with a technology focus and thus neglect the (dynamically changing) organization they should support. ODP addresses important issues, but came at a time when distributed applications were usually rather simple: ODP was considered overkill.

Layered Architectures vs. Component Architectures

Before we introduce concrete reference architectures, it is worth recalling the two complementary flavors:

- **Layered reference architectures** serve as a blueprint for layered software architectures. Both arrange sets of functions into layers that act as virtual machines: only the “what” (provided functionality and how to access it) must be known to users in higher layers, whereas the internal “how” (realization) is hidden and can be independently modified. The layer stack represents the range from higher to lower function sets, where higher means “closer to what users and applications need” and lower means “closer to what hardware provides”. Strict variants preclude higher layer components to access lower layers except for the one immediately below. Recent research has concentrated on approaches for automatic, selective custom configuration of the entire layer stack, according to the needs of applications—this trend is important in the UC world where dedicated, resource-poor UC nodes cannot host fat all-purpose layers.

- **Component reference architectures** take a birds-eye view on the world addressed. They define a number of cooperating components or rather component types, and specify inter-component cooperation at a certain level of detail. Again, a kind of art of right-sizing exists: too few component types do not really help to understand and discern relevant roles and specializations common to the world addressed, too many component types lead to overly complex architectures and problems in matching reference and reality.

Although we focus on the Computer Networks / Distributed Systems aspects of UC in the remainder of this chapter, readers should note that the entire book represents a holistic approach.

Why Component Reference Architectures are Important for UC

The OSI reference architecture assumes a network consisting of rather homogeneous nodes, namely general-purpose computers with ‘sufficient’ CPU and memory capacity. Accordingly, a common definition of a computer network reads as follows:

\[
\text{A computer network } CN \text{ is a set of autonomous nodes } AN, \text{ each of which disposes of CPU(s) and memory, plus a Communication Subsystem CSS capable of exchanging messages between any of the nodes: } CN := \{AN\} \cup CSS.
\]

In the definition, “all nodes are created equal”. At a closer look, computer networks rely on four mandatory constituents of nodes (ANs):

1. **Communication capability**: The capacity of exchanging messages with other nodes through the CSS.
2. **Address**: A unique identifier that can be used to specify the recipient or sender of messages.
3. **Processor**: A general purpose CPU.
4. **Memory**: Means for storing—at least—incoming messages.

In a UC world, resource scarcity and the special-purpose nature of many nodes are key issues.

A holistic UC approach must scale from servers to sensors and support the consideration of smart labels etc. The definition of a UC node must be different from the one above—the four constituents now read as follows:

1. **Communication** is mandatory, but may be passive (cf. passive RFID tags)
2. **Address** is not necessarily a unique identifier; for example, in a sensor network, a random node out of a redundant set with identical address may provide a certain functionality
3. **Processor** becomes an *optional* constituent
4. **Memory** becomes an *optional* constituent, too

With the above modifications, not all nodes are *autonomous (ANs)* any more.

**Proposed UC Component Reference Architectures**

The definition introduces a first possibility for distinguishing nodes as components of an application, that is, from the component architecture point of view. However, it only discerns between existing versus missing fundamental characteristics. More interesting is the aspect of different roles that nodes can play in the network—not application specific roles, but fundamental roles in the set of cooperating resources. Thus UC systems will take on more complex node topologies than what was considered in the eras of simple interprocess communication and client-server computing. In addition, a holistic approach needed for UC systems raises issues such as security, which are important when trying to find important node types at different levels of granularity.

One of the first proposals for a UC component reference architecture was made by the Fraunhofer research institute FOKUS in Berlin. They did not distinguish different node types that would assume different roles, but identified important roles that each UC node may potentially assume. Their concept is coined *I-Centric Services* and achieved a certain level of influence on the industrial Object Management Group (OMG). In their view, a UC node (usually a software service) should provide standard interfaces for four major issues:

1. **Discovery** of peers in a spontaneous, configuration-free manner
2. **Maintainance**, i.e., software update and revision
3. **Reservation**, that is, pre-allocation of some of the node’s resources as a basis for service guarantees
4. **Configuration** as a means for customizing the service for a dedicated role

Nodes that conform to these interfaces are called *super distributed objects (SDO)* in this proposal.

We will discuss another component architecture in some more detail since it attempts to discern between more specific roles of UC nodes. It was developed in the Telecooperation Group at the Technische Universität Darmstadt and is called *Mundo*, see Figure 4. *Mundo* distinguishes five different node types: *Me, Us, It, We, and They*.

*Me (Minimal Entity):* *Mundo* emphasizes the importance of a distinct personal UC node, that is the device tightly associated with its user: the Me. Every user uses exactly only one *Me* at any time. The rationale is rooted in the envisioned ubiquity of computer support in everyday life: if every step that one takes is potentially computer supported and controlled, then humans need a high level of trust that the computers “do the right thing”. For instance, users will want to make sure
that their actions are only recorded and disclosed to the degree they consent to or that is legally imposed. As another example, they want to be sure that they only trigger actions which they understand in their legal, financial, and other consequences and that they agree to. To this end, the Mundo researchers propose to conceptualize a single, truly owned UC node type that acts in the user’s stead and controls when, how, and to what extent other UC node types are invited or chartered to participate in actions. Since computer use becomes ubiquitous, such a personally-owned node type must be carried along virtually at all times. This imposes strong requirements with respect to miniaturization, robustness, and the conflicting goals of (a) the impossibility to falsify or duplicate such a node, and (b) the possibility to replace it easily in case of theft or failure. An important research questions is concerned with the minimum functionality of a Me.

Me nodes are considered as the representation of their users in the digital world—a digital persona involved in all user activities. It is a small wearable computer with minimal functionality. In order to support interaction with UC environments in a sensible way, the term minimal must be associated with a set of specific requirements regarding size, identity, security, interaction, context awareness, and networking. The design was guided by the principle that the minimal feature set of a system is determined by the worst-case environmental conditions under which the application must run satisfactorily (Satyanarayanan, 2001). This leads to a focus on speech based interaction and it is described in detail by Aitenbichler, Kangasharju, and Mühlhäuser (2004). Any Me can augment its capabilities through association with other entities of the Mundo architecture as described next.

Us (Ubiquitous aSSociable object): Minimization pressure will not permit feature-rich Mes. Hence, they must be able to connect to other mobile devices or devices embedded into the environment to offer more powerful services to their users, such as large display space. This process is called association and such devices are called ubiquitous aSSociable objects (Us). A Us is a computing device that extends the user’s personal environment by adding storage, processing capacity, displays, interaction devices, and so forth. During association, the Me sends authentication information to the Us, sets up a secure communication link, and personalizes the Us to suit the user’s preferences and needs. For privacy reasons, any personalization of a Us becomes automatically unavailable if it is out of range of the user’s Me.

Ir (smart iTem): There are also numerous smart items that do not support association that would classify them as Us. Vending machines, goods equipped with radio frequency IDs, and landmarks with “what is” functionality are just a few examples. Such devices are called smart items (Irs). An Ir is any digital or real entity that has an identity and can communicate with a Us or the Me. Communication may be active or passive. Memory and computation capabilities are optional (cf. the four constituents of a UC node described previously).

We (Wireless group Environment): Ad-hoc networking is restricted to an area near to the user of a Me device, as connections with remote services will involve a non ad hoc network infrastructure. The functionality of a wireless group environment is to bring together two or more personal environments consisting of a Me and arbitrary Us entities each. It enables cooperation between the devices and also allows for sharing
and transferring hardware (e.g., Us devices) and software or data between We users.

**THEY (Telecooperative Hierarchical ovErlaY)** stands for the backbone infrastructure as part of the Mundo component architecture. It connects users to the (nonlocal) world, and delivers services and information to the user. The THEY integrates different physical networks and provides transparent data access to users. Frequently used data may be cached on Us devices.

**UC Layered Reference Architectures**

Many actual UC projects are based on a layered architecture. Most of them are just first approaches to software architectures, only a few of them are intended to serve as a crystallization point for the community and future standards. Nevertheless, one of them may turn out to be so successful that a future reference architecture will evolve from it. We will concentrate on a small selection of the few projects that have a general reference model in mind. They concentrate on different challenges or foci, that is their findings will have to be merged if a holistic layered architecture is to be derived.

A first focus is the enterprise modeling that ODP already addressed. A reference architecture worth mentioning here is ODSI, the so-called open distributed services infrastructure (Bond, 2001). Although already outdated, ODSI was influential since it fostered the move away from ODP’s more top-down approach to a component-based, that is service based approach that supports the concept of applications being compositions of services.

Other reference architectures emphasize Smart Environments. Two facets are important and investigated—still—in different camps even as to the work on reference architectures: smart information spaces and smart physical spaces. By smart information spaces, we mean environments which concentrate on cooperative treatment of IT- and data/media centric work (cf. Mark Weiser’s three initial UC devices). Smart physical spaces are often called smart spaces or more specifically smart houses, labs, offices, homes etc. Work on these kinds of environments emphasizes the tangible, physical (computer-augmented) objects to be handled.

As for smart information spaces, an interesting reference architecture was proposed in the LifeSpaces project in South Australia (Bright & Vernik, 2004). Their architecture incorporates some of the findings from ODSI and distinguishes four layers:

1. **Enterprise model**: This layer supports rules, processes, and organizational models of roles and services in the enterprise.
2. **Coordination and control including interaction support**: On this layer, a shared and persistent event space of limited capacity, and an agent-based workspace infrastructure are offered.
3. **Enterprise bus**: This term refers to a communication layer based on the publish/subscribe paradigm.
4. **The service layer**: Here, the core functionality is represented by easily composable services. An enterprise bus is offered for services to communicate and cooperate; this bus connects so-called peers which host the services.

As for smart physical spaces, a prominent example is the reference architecture developed by the Gator Tech Smart House project of the University of Florida (see Figure 5). The reference architecture depicted is a more recent version of what was published by Helal, Mann, El-Zabadani, King, Kaddoura, and Jansen (2005) and is included by courtesy of the authors (the commercial version is called Atlas now). For more information, the reader may consult the group’s Web Site at [www.icta.ufl.edu](http://www.icta.ufl.edu) or the Atlas Web site at [www.pervasa.com](http://www.pervasa.com). The architecture emphasizes sensors (plus actuators) and networked embedded devices at the lowest layer as the hardware foundation of UC...
applications. The OSGI standard is exploited for customizing and maintaining these sensors and embedded devices in a dedicated second layer. The third layer contains three large parts which reflect major insights into the nature of the UC world (note that these insights have a large influence on the present book, too):

- **The context management layer** reflects the importance of context-awareness for UC as a whole, as discussed in the preface of the book;
- **The service layer** reflects services (and service-oriented architectures, SOA) as the dominating paradigm for building autonomous software components in a UC setting;
- **The knowledge layer** reflects the fact that large-scale service composition cannot rely on standardized interfaces that are distributed prior to software (service) development; rather, service discovery and service interaction must rely on machine readable descriptions of the service semantics available at runtime;
- Due to the strictly service-oriented concept used, application development boils down to service composition; the top layer offers corresponding tools.

In conclusion, it should have become clear that both a component based and a layered reference architecture, if widely accepted, would be important steps from UC islands towards truly global UC. The reference architectures presented could serve as a basis for better communication among the UC protagonists and for the necessary standards.

Chapter 1.2
Ubiquitous Computing and the Concept of Context

INTRODUCTION

Mark Weiser (1991) envisioned in the beginning of the 1990s that ubiquitous computing, intelligent small-scale technology embedded in the physical environment, would provide useful services in the everyday context of people without disturbing the natural flow of their activities.

From the technological point of view, this vision is based on recent advances in hardware and software technologies. Processors, memories, wireless networking, sensors, actuators, power, packing and integration, optoelectronics, and biomaterials have seen rapid increases in efficiency with simultaneous decreases in size. Moore’s law on capacity of microchips doubling every 18 months and growing an order of magnitude every five years has been more or less accurate for the last three decades. Similarly, fixed network transfer capacity grows an order of magnitude every three years, wireless network transfer capacity every 5 to 10 years, and mass storage every 3 years. Significant progress in power consumption is less likely, however. Innovations and breakthroughs in distributed operating environments, ad hoc networking, middleware, and platform technologies recently have begun to add to the ubiquitous computing vision on the software side.

Altogether, these technological advances have a potential to make technology fade into the background, into the woodwork and fabric of everyday life, and incorporate what Weiser (1991) called natural user interfaces. Awareness of situational factors (henceforth, the context) consequently was deemed necessary for this enterprise. This article looks at the history of the concept of context in ubiquitous computing and relates the conceptual advances to advances in envisioning human-computer interaction with ubiquitous computing.
BACKGROUND

Ubiquitous Computing Transforms Human-Computer Interaction

Human-computer interaction currently is shifting its focus from desktop-based interaction to interaction with ubiquitous computing beyond the desktop. Context-aware services and user interface adaptation are the two main application classes for context awareness. Many recent prototypes have demonstrated how context-aware devices could be used in homes, lecture halls, gardens, schools, city streets, cars, buses, trams, shops, malls, and so forth.

With the emergence of so many different ways of making use of situational data, the question of what context is and how it should be acted upon has received a lot of attention from researchers in HCI and computer science. The answer to this question, as will be argued later, has wide ramifications for the design of interaction and innovation of use purposes for ubiquitous computing.

HISTORY

Context as Location

In Weiser’s (1991) proposal, ubiquitous computing was realized through small computers distributed throughout the office. Tabs, pads, and boards helped office workers to access virtual information associated to physical places as well as to collaborate over disconnected locations and to share information using interfaces that take locational constraints sensitively into account. Although Weiser (1991) never intended to confine context to mean merely location, the following five years of research mostly focused on location-based adaptation. Want et al. (1992) described the ActiveBadge, a wearable badge for office workers that could be used to find and notify people in an office. Weiser (1993) continued by exploring systems for sharing drawings between disconnected places (the Tivoli system). Schilit et al. (1994) defined context to encompass more than location—to include people and resources as well—but their application examples were still mostly related to location sensing (i.e., proximate selection, location-triggered reconfiguration, location-triggered information, and location-triggered actions). Want, et al. (1995) added physical parameters like time and temperature to the definition. Perhaps the best-known mobile application developed during this location paradigm era was the CyberGuide (Long et al., 1996), an intelligent mobile guide that could be used to search for nearby services in a city. This paradigm was also influential in the research on Smart Spaces, such as intelligent meeting rooms.

The Representational Approach to Context

Although the idea that location equals context was eventually dismissed, many researchers coming from computer science still believed that contexts were something that should be recognized, labeled, and acted upon (Schmidt et al., 1998). Here, context was supposed to be recognized from sensor data, labeled, and given to applications that would use it as a basis for adaptation. Dey et al.’s (1999) five Ws of context—Who, Where, When, What, and Why—extended this approach and demonstrated convincing examples of how a labeled context could be used for presenting, executing, and tagging information. Tennenhouse’s (2000) proactive computing paradigm endorsed a similar way of thinking about context, emphasizing the role of computers in doing real-time decisions on behalf of (or pro) the user. A somewhat similar approach that also attempts to delegate decision-making responsibility to intelligent systems is taken by the Ambient Intelligence (AmI) technology program of the European Union (ISTAG). One part of the AmI vision entails intelligent agents that assume some of the control responsibility from the users.
The latest widely referred to definition was given by Dey et al. (2001), who defined context as “any information that characterizes a situation related to the interaction between users, applications, and the surrounding environment” (p. 106). Satyanarayanan’s (2001) formulation of pervasive computing also belongs to this line of thinking, but the author has chosen to avoid defining context and merely admits that it is rich and varies.

In his review of context definitions over the years, Dourish (2004) calls this the representational approach to context. Recent work within this branch has come close to finding the limits to recognizing and labeling contexts. For example, simple physical activities of a person in a home environment can be recognized with about 80-85% accuracy (Intille et al., 2004), as can be the interruptability of a person working in an office (Fogarty et al., 2004). Some critics have drawn parallels from this enterprise to problems encountered in strong AI (Erickson, 2002).

**FUTURE TRENDS**

**New Directions Inspired by Human and Social Sciences**

By the year 1996, other approaches to context were beginning to emerge. Wearable computing (Mann, 1996) looked at personal wearable computers able to help us remember and capture our everyday experiences through video and sound recording of context. Tangible bits (Ishii & Ullmer, 1997), although inspired by ubiquitous computing, looked at context not as something that had to be reacted upon but as surroundings of the user that could be augmented with tangible (i.e., graspable) computers and ambient media that display digital information using distraction-free output channels.

More recently, researchers have started to emphasize the social context and issues in people’s practices and everyday conduct. These approaches give special consideration to activities that people engage in and highlight their dynamic nature, different from the labeling-oriented representational approach. Activity-centered approaches emphasize both turn taking in communication between the user and the applications (Fischer, 2001) and acknowledge the situated and time-varying nature of the needs that a user has in his or her life (Greenberg, 2001). This line of research highlights the difficulties that exist in making correct inferences about a user’s tasks through sensor information. Considerations of social issues in ubiquitous computing design include questions of how to fit computation intelligence into people’s routines in an unremarkable manner (Tolmie et al., 2002) and how people’s patterns of interaction with humans and computers change when computationally augmented artifacts are adopted into use. Yet another emerging idea from HCI addresses specifically the aim to be free from distraction; that is, when it is appropriate to interrupt the user at his or her present task. Some call systems with such inferring capabilities *attentive user interfaces* (Vertegaal, 2003).

**CONCLUSION**

HCI in ubiquitous computing has been both inspired and constrained by conceptual developments regarding the concept of context. Weiser’s (1991) initial work caused researchers to conceive context narrowly as encompassing mainly location and other static, easily measurable features of a user’s context. After about five years of research, the restrictiveness of this definition was realized, and broader definitions were formulated. Still, context mainly was pursued by computer scientists and seen as something that must be labeled and reacted upon to adapt user interfaces. More recent work by human and social scientists has emphasized the role of user studies and theoretical reasoning in understanding what context entails in a particular application.
REFERENCES

**KEY TERMS**

**Attentive User Interfaces:** AUIs are based on the idea that modeling the deployment of user attention and task preferences is the key for minimizing the disruptive effects of interruptions. By monitoring the user’s physical proximity, body orientation, eye fixations, and the like, AUIs can determine what device, person, or task the user is attending to. Knowing the focus of attention makes it possible in some situations to avoid interrupting the users in tasks that are more important or time-critical than the interrupting one.

**Context:** That which surrounds and gives meaning to something else. (Source: The Free On-line Dictionary of Computing, http://foldoc.doc.ic.ac.uk/foldoc/)

**Peripheral Computing:** The interface attempts to provide attentionally peripheral awareness of people and events. Ambient channels provide a steady flow of auditory cues (i.e., a sound like rain) or gradually changing lighting conditions.

**Pervasive Computing:** Technology that provides easy access to information and other people anytime and anywhere through a mobile and scalable information access infrastructure.

**Proactive Computing:** A research agenda of developing interconnected devices and agents, equipped with faster-than-human-speed computing capabilities and means to affect real-world phenomena that a user can monitor and steer without a need to actively intervene in all decision-making situations. By raising the user above the traditional human-computer interaction loop, efficiency and freedom from distraction are expected to be enhanced.

**Tangible Bits:** According to Hiroshi Ishii of MIT, “the smooth transition of users’ focus of attention between background and foreground using ambient media and grasparable objects is a key challenge of Tangible Bits” (p. 235).

**Tangible User Interfaces:** Systems that give a physical form to digital information through augmenting tools and grasparable objects with computing capabilities, thus allowing for smooth transitions between the background and foreground of the user’s focus of attention.

**Unremarkable Computing:** An approach that focuses on designing domestic devices that are unremarkable to users. Here, unremarkable is understood as the use of a device being a part of a routine, because, it is believed, routines are invisible in use for those who are involved in them.

**Wearable Computing:** Technology that moves with a user and is able to track the user’s motions both in time and space, providing real-time information that can extend the user’s knowledge and perception of the environment.
INTRODUCTION

Although gender differences in a technological world are receiving significant research attention, much of the research and practice has aimed at how society and education can impact the successes and retention of female computer science professionals. The possibility of gender issues within software, however, has received almost no attention, nor has the population of female end users. However, there is relevant foundational research suggesting that gender-related factors within a software environment that supports end-user computing may have a strong impact on how effective male and female end users can be in that environment. Thus, in this article, we summarize theory-establishing results from other domains that point toward the formation of grounded hypotheses for studying gender differences in end-user computing.

There has been much background research relevant to human issues of end-user computing, which we define here as problem-solving using computer software, also termed end-user programming in some of the literature (e.g., Blackwell, 2002; Green & Petre, 1996; Nardi, 1993). (See the glossary for definitions of these and related terms.) Despite this, few researchers have considered potential gender HCI issues and gender differences that may need to be accounted for in designing end-user computing environments. The most notable exception is Czerwinski’s pioneering research on the support of both genders in navigating through 3-D environments (Czerwinski, Tan, & Robertson, 2002; Tan, Czerwinski, & Robertson, 2003). Although individual differences, such
as experience, cognitive style, and spatial ability, are likely to vary more than differences between gender groups, evidence from Czerwinski’s work as well as work in other domains, such as psychology and marketing, has found gender differences relevant to computer usage. In fact, some research has shown that some software is (unintentionally) designed for males (Huff, 2002).

One reason gender HCI issues in end-user computing are important is that ignorance of gender issues has already proven to be dangerous: today’s low percentage of computer science females (Camp, 1997) has been directly attributed to the past unawareness of gender issues in computer science education and in the workforce. There is a risk that if gender HCI issues in end-user computing environments are ignored, a similar phenomenon could occur with female end users.

**WHAT COULD GO WRONG?**

What gender differences might matter in the design of end-user computing environments? Consider the following scenario in one particular end-user computing environment.

Imagine a female teacher engaged in preparing a spreadsheet to track her students’ scores and to calculate ways of providing students with the best grades. Part of her process of preparing her spreadsheet is to test the spreadsheet. While she is engaged in testing, the system surprises her by decorating some of the spreadsheet cells, as in Figure 1.

The surprises were intentionally placed into the software by the designers relying on a strategy for end-user computing environments called Surprise-Explain-Reward (Wilson et al., 2003). The surprise, which was intended to capture the teacher’s attention and arouse her curiosity, reveals the presence of an “information gap” (Lowenstein, 1994). In this case the system is using the surprise to interest her in assertions (Burnett et al., 2003), which she can use to guard against future errors by specifying, for example, that the value of a cell calculating a grade average should always fall between 0 and 100.

What could go wrong in surprising the user? According to Lowenstein’s information gap theory, a user needs to have a certain level of confidence in order to reach a useful level of curiosity (Lowenstein, 1994). However, given documented gender differences in computer confidence (Busch, 1995; Huff, 2002), the teacher’s level of computer confidence could interfere with the surprise’s ability to capture her interest.

Returning to our scenario, suppose for this particular user, the surprise is effective at arousing her curiosity, she looks to the object that surprised her (the assertion) for an explanation. The explanation, viewed through a tooltip, includes the semantics, possible actions she can take (regarding the assertion), and the future reward(s) of taking the action. See Figure 1.

What could go wrong with the explanation? According to one theory, males and females process information differently (Meyers & Sternthal, 1991; O’Donnell & Johnson, 2001), and thus both the presentation and the content of the explanation may impact its effectiveness for males versus females. If the information needed by the user is not effectively communicated, the user’s ability to problem solve is likely to be reduced.

Another role of the explanation is to help users make a reasonably accurate assessment of the risk in taking some action—but since males and females differ in their perceptions of risk (Byrnes, Miller, & Schafer, 1999), the explanation may need to serve these two populations differently in this respect as well. (An example of risk may be the fear that the user will lose their work if they try a certain feature.) If one gender perceives an explanation of a feature as communicating higher levels of risk than another, the users with higher risk perceptions may avoid supposedly “risky” features that may be important to overall effectiveness.
Perhaps the most important role of explanations is to make clear the rewards of using particular features of the software. Providing information about rewards in the explanation is consistent with the implications of the Model of Attention Investment (Blackwell, 2002), an analytic model of user problem-solving behavior that models the costs, benefits, and risks users weigh in deciding how to complete a task. An implication of this model is that if the system provides the user an idea of future benefits, users can better assess if the cost of using a feature (here assertions) is worth their time. The reward aspect of the strategy refers to rewards such as the automatic detection of errors, which is depicted by the red circle around HomeWork1’s erroneous value in Figure 1.

What could go wrong with rewards? Since males and females are often motivated by different factors, there may be gender differences in what actually is a perceived “reward.” If the rewards are only tailored to one gender’s perceptions of rewards, the other gender may not be motivated to use the devices that will help them be effective. In this end-user computing scenario, potential problems arose that may be addressable within the end-user computing software itself. Four issues that arose here were (1) software features whose effects depend upon users’ computer confidence (discussed in the section on confidence), (2) the software’s ability to communicate effectively with users (discussed in support), (3) the possibility of a user’s perception of risk interfering with the user choosing to use appropriate features (discussed in motivation), and (4) possible differences between a user’s actual motivations and the software’s attempt to “reward” users for using particular features (discussed in motivation). These issues together form a useful organizational framework for considering gender HCI.

CONFIDENCE

This document uses the term “confidence” for the interrelated concepts of self-confidence, self-efficacy, overconfidence, and perceived risk.

From the field of computer science, there is substantial evidence of low confidence levels as computer science females compare themselves to the males (Margolis, Fisher, & Miller, 1999). Of particular pertinence to end-user computing, however, is the evidence showing that low confidence relating to technology is not confined to computer science females (Busch, 1995; Huff, 2002; Torkzadeh & Van, 2002).

As a measure of confidence, researchers often use self-efficacy, as was done in the Busch study. Self-efficacy is belief in one’s capabilities to perform a certain task (Bandura, 1994). There is specific evidence that low self-efficacy impacts
attitudes toward a new software package prior to its use (Hartzel, 2003). Taken together, this research suggests that a first experience with end-user computing software can impact attitudes which may in turn impact users’ future choices to (or not to) use some features in their software.

Overconfidence matters too, because it can prevent people from suspecting errors, leading to misplaced trust in erroneous programs. In particular, overconfidence in spreadsheet correctness is common (Panko, 1998). There is evidence (Lunderberg, Fox, & Punchochar, 1994) suggesting gender differences in overconfidence just as in under confidence. Hence, designing methods to help alleviate overconfidence in end-user computing needs to be carefully targeted specifically toward overconfident users.

Perception of risk is tied to confidence, and impacts the decisions people make. According to the attention investment model (a model of how users allocate their attention in problem solving) (Blackwell, 2002), a user may choose not to follow through a particular action, if they decide that the costs and/or risks are too high in relation to the benefits of taking that action. Perception of risk thus plays an important role in a user’s decision-making about whether to use some features, and can lead to differences in actual behavior.

Differences in perception of risk have been tied to gender. For example, a meta-analysis of 150 studies on gender and risk taking found that females engaged in less risk taking than males (Byrnes, Miller, & Schafer 1999). The meta-analysis did not address risks of computer use directly. However, it did find that intellectual risk taking, defined as activities involving mathematical or spatial reasoning skills, was greater in males than in females (Byrnes, Miller, & Schafer 1999).

To obtain evidence about whether confidence might directly impact gender HCI issues for end-user computing environments, we conducted a preliminary think-aloud study in which participants attempted to debug two spreadsheets, given the support of Surprise-Explain-Reward devices (Beckwith & Burnett, 2004). To our surprise, the females’ confidence levels dropped over the course of the study much more than did the males’ confidence levels. This result suggests that end-user computing environment itself—which, like other end-user computing environments, was designed without knowledge of gender-related HCI principles—is not currently serving the females’ needs as well as the males’. A subsequent follow-up study (Beckwith et al., 2005) confirmed this: in the spreadsheet paradigm, ties were found between females’ confidence issues and low utilization of features aimed to support problem solving, resulting in effectiveness problems.

**SUPPORT**

We will use the term “support” to mean built-in aspects of the software, such as on-line help systems and Figure 1’s tooltips that help users learn or understand the environment.

The system’s approach to help users achieve mastery in remembering the software’s devices may depend on a user’s learning style. One survey of university students found that students with an “abstract random” learning style were significantly more likely to be female and, as a result, could find computer-based instruction ineffective for learning (Ames, 2003). Other researchers have also found gender differences in learning styles (Heffler, 2001; Severiens & ten Dam, 1997). One implication of these findings is that end-user computing may need to support several learning styles, especially if some users are easily dissuaded by support devices not sensitive to their learning style.

Problem-solving style also shows gender differences, at least for computer games (Kafai, 1998). Researchers found that, unlike boys, rather than working in a linear fashion through the game, girls prefer to explore and move freely about a game (Gorriz & Medina, 2000). In another difference in problem-solving style, boys’ games
Gender and End-User Computing

typically depend upon competition, whereas girls prefer collaboration and working together (Kafai, 1998). For end-user computing environments, these problem-solving differences suggest differences in the support provided by the system. For example, supporting both linear and non-linear problem-solving styles and providing avenues for both competition and collaboration may be important for software’s success at supporting both genders adequately.

Finally, the theory of selectivity suggests gender differences which may impact how users process the information support devices provide. The theory of selectivity, from research in the area of marketing, states that males and females differ in their information processing strategies (Meyers & Sternthal, 1991; O’Donnell & Johnson, 2001). According to this theory of selectivity, females are more likely to employ elaborative information processing strategies, regardless of whether the task is simple or complex in nature. Males, however, are more likely to select heuristic processing strategies that minimize cognitive effort and reduce information load for simple tasks, switching to an elaborative strategy only on more complex tasks.

These gender differences have been shown to impact diverse software-related activities, ranging from users’ perceptions of Web sites used for e-commerce (Simon, 2001) to users’ performance on auditing tasks (O’Donnell & Johnson, 2001). For end-user computing environments, this research may have implications for informing end users of important information via the software’s support devices.

MOTIVATION

Research has shown that computer science females are motivated by how technology can help other people, whereas males tend to enjoy technology for its own sake (Margolis, Fisher, & Miller, 1999). These differences are also found with other females who use technology, such as architects, NASA scientists, and filmmakers. One study (Brunner, Bennett, & Honey, 1998) found that females described technological objects as tools to help integrate personal and professional lives and to facilitate creativity and communication, whereas males described them as technological devices to increase command and control over nature and one another. The gender differences found in that study are summarized in Table 1.

The technology acceptance model (TAM) (Morris & Dillon, 1997; Venkatesh & Morris, 2000) provides a model of users’ acceptance and usage behavior of technology. According to TAM, user acceptance, and ultimately technology use, is determined by two key beliefs: perceived usefulness and perceived ease of use (Venkatesh & Morris, 2000). “Perceived usefulness” is the degree to which a user believes that using the system will enhance their performance, and “perceived ease of use” is the degree to which the user believes that using the system will be free of effort. According to one study, the relative importance of each differs by gender (Venkatesh & Morris, 2000); women were more influenced by perceived ease of use whereas men were more influenced by perceived usefulness.

FUTURE TRENDS AND CONCLUSION

To date, there has been little research on how the design of software itself may interact with gender differences. Still, foundational work from several domains strongly suggests that such differences may have critical impacts on users’ success in end-user computing.

Although research is beginning to emerge providing some insights into gender’s importance in end-user computing environments, it is still largely an open question. Also open are questions of what specific types of differences matter in such environments and what amelioration strategies are possible.
Gender and End-User Computing

To help provide a foundation upon which researchers interested in these issues can build, this article has drawn from five domains to summarize literature relevant to these questions. All of the literature surveyed identifies one or more issues that potentially impact end users’ success that are also potentially addressable within the software system. Together, the open questions and survey are intended to provide a foundation for future investigation.

Chapter 1.4
The Theoretical Framework of Cognitive Informatics

Yingxu Wang
University of Calgary, Canada

ABSTRACT

Cognitive Informatics (CI) is a transdisciplinary enquiry of the internal information processing mechanisms and processes of the brain and natural intelligence shared by almost all science and engineering disciplines. This article presents an intensive review of the new field of CI. The structure of the theoretical framework of CI is described encompassing the Layered Reference Model of the Brain (LRMB), the OAR model of information representation, Natural Intelligence (NI) vs. Artificial Intelligence (AI), Autonomic Computing (AC) vs. imperative computing, CI laws of software, the mechanism of human perception processes, the cognitive processes of formal inferences, and the formal knowledge system. Three types of new structures of mathematics, Concept Algebra (CA), Real-Time Process Algebra (RTPA), and System Algebra (SA), are created to enable rigorous treatment of cognitive processes of the brain as well as knowledge representation and manipulation in a formal and coherent framework. A wide range of applications of CI in cognitive psychology, computing, knowledge engineering, and software engineering has been identified and discussed.

INTRODUCTION

The development of classical and contemporary informatics, the cross fertilization between computer science, systems science, cybernetics, computer/software engineering, cognitive science, knowledge engineering, and neuropsychology, has led to an entire range of an extremely interesting and new research field known as Cognitive Informatics (Wang, 2002a, 2003a, b, 2006b; Wang, Johnston & Smith 2002; Wang & Kinsner, 2006). Informatics is the science of information that studies the nature of information; it’s processing, and ways of transformation between information, matter, and energy.

Definition 1. Cognitive Informatics (CI) is a transdisciplinary enquiry of cognitive and information sciences that investigates the internal in-
formation processing mechanisms and processes of the brain and natural intelligence, and their engineering applications via an interdisciplinary approach.

In many disciplines of human knowledge, almost all of the hard problems yet to be solved share a common root in the understanding of the mechanisms of natural intelligence and the cognitive processes of the brain. Therefore, CI is a discipline that forges links between a number of natural science and life science disciplines with informatics and computing science.

The structure of the theoretical framework of CI is described in Figure 1, which covers the Information-Matter-Energy (IME) model (Wang, 2003b), the Layered Reference Model of the Brain (LRMB) (Wang, Wang, Patel & Patel, 2006), the Object-Attribute-Relation (OAR) model of information representation in the brain (Wang, 2006h; Wang & Wang, 2006), the cognitive informatics model of the brain (Wang, Liu, & Wang, 2003; Wang & Wang, 2006), Natural Intelligence (NI) (Wang, 2003b), Autonomic Computing (AC) (Wang, 2004), Neural Informatics (NeI) (Wang, 2002a, 2003b, 2006b), CI laws of software (Wang, 2006f), the mechanisms of human perception processes (Wang, 2005a), the cognitive processes of formal inferences (Wang, 2005c), and the formal knowledge system (Wang, 2006g).

In this article, the theoretical framework of CI is explained in the fundamental theories of CI section. Three structures of new descriptive
mathematics such as Concept Algebra (CA), Real-Time Process Algebra (RTPA), and System Algebra (SA) are introduced in the denotational mathematics for CI in order to rigorously deal with knowledge and cognitive information representation and manipulation in a formal and coherent framework. Applications of CI are discussed, which covers cognitive computing, knowledge engineering, and software engineering. Then, it draws conclusions on the theories of CI, the contemporary mathematics for CI, and their applications.

THE FUNDAMENTAL THEORIES OF CI

The fundamental theories of CI encompass 10 transdisciplinary areas and fundamental models, T1 through T10, as identified in Figure 1. This section presents an intensive review of the theories developed in CI, which form a foundation for exploring the natural intelligence and their applications in brain science, neural informatics, computing, knowledge engineering, and software engineering.

The Information-Matter-Energy Model

Information is recognized as the third essence of the natural world supplementing to matter and energy (Wang, 2003b), because the primary function of the human brain is information processing.

Theorem 1. A generic worldview, the IME model states that the natural world (NW) that forms the context of human beings is a dual world: one aspect of it is the physical or the concrete world (PW), and the other is the abstract or the perceptive world (AW), where matter (M) and energy (E) are used to model the former, and information (I) to the latter, that is:

\[
\text{NW} \equiv \text{PW} \parallel \text{AW} = p(M, E)\parallel a(I) = n(I, M, E)
\]  

where \(\parallel\) denotes a parallel relation, and \(p, a,\) and \(n,\) are functions that determine a certain \(PW, AW,\) or \(NW,\) respectively, as illustrated in Figure 2.

According to the IME model, information plays a vital role in connecting the physical world with the abstract world. Models of the natural world have been well studied in physics and other natural sciences. However, the modeling of the abstract world is still a fundamental issue yet to be explored in cognitive informatics, computing, software science, cognitive science, brain sciences, and knowledge engineering. Especially the relationships between I-M-E and their transformations are deemed as one of the fundamental questions in CI.

Corollary 1. The natural world \(NW(I, M, E),\) particularly part of the abstract world, \(AW(I),\) is cognized and perceived differently by individuals because of the uniqueness of perceptions and mental contexts among people.

Corollary 1 indicates that although the physical world \(PW(M, E)\) is the same to everybody, the natural world \(NW(I, M, E)\) is unique to different individuals because the abstract world \(AW(I),\) as a part of it, is subjective depending on the information an individual obtains and perceives.

Corollary 2. The principle of transformability between IME states that, according to the IME model, the three essences of the world are predicated to be transformable between each other as described by the following generic functions \(f_1\) to \(f_6:\)

\[
I = f_1(M)
\]

\[
M = f_2(I) = f_1^{-1}(I)
\]

\[
I = f_3(E)
\]

\[
NW = PW || AW = p(M, E) || a(I) = n(I, M, E)
\] (1)

\[
I = f_1(M)
\]

\[
M = f_2(I) = f_1^{-1}(I)
\]

\[
I = f_3(E)
\]
\[ E = f_4(I) \cdot f_3^{-1}(I) \quad (2.4) \]
\[ E = f_5(M) \quad (2.5) \]
\[ M = f_6(E) \cdot f_5^{-1}(E) \quad (2.6) \]

where a question mark on the equal sign denotes an uncertainty if there exists such a reverse function (Wang, 2003b).

Albert Einstein revealed Functions \( f_5 \) and \( f_6 \), the relationship between matter (m) and energy (E), in the form \( E = mC^2 \), where \( C \) is the speed of light. It is a great curiosity to explore what the remaining relationships and forms of transformation between I-M-E will be. To a certain extent, cognitive informatics is the science to seek possible solutions for \( f_1 \) to \( f_4 \). A clue to explore the relations and transformability is believed in the understanding of the natural intelligence and its information processing mechanisms in CI.

**Definition 2.** Information in CI is defined as a generic abstract model of properties or attributes of the natural world that can be distinctly elicited, generally abstracted, quantitatively represented, and mentally processed.

**Definition 3.** The measurement of information, \( I_k \), is defined by the cost of code to abstractly represent a given size of internal message \( X \) in the brain in a digital system based on \( k \), that is:

\[
I_k = f : X \rightarrow S_k = \lfloor \log_k X \rfloor \tag{3}
\]

where \( I_k \) is the content of information in a \( k \)-based digital system, and \( S_k \) is the measurement scale based on \( k \). The unit of \( I_k \) is the number of \( k \)-based digits (Wang, 2003b).

Equation 3 is a generic measure of information sizes. When a binary digital representation system is adopted, that is \( k = b = 2 \), it becomes the most practical one as follows.

**Definition 4.** The metalevel representation of information, \( I_b \), is that when \( k = b = 2 \), that is:

---

**Figure 3. LRMB model**

![LRMB model](image-url)
\[ I_b = f : X \rightarrow S_b \]
\[ = [\log_2 X] \]  

where the unit of information, \( I_b \), is a bit.

Note that the bit here is a concrete and deterministic unit, and it is no longer probability-based as in conventional information theories (Bell, 1953; Shannon, 1948). To a certain extent, computer science and engineering is a branch of modern informatics that studies machine representation and processing of external information; while CI is a branch of contemporary informatics that studies internal information representation and processing in the brain.

Theorem 2. The most fundamental form of information that can be represented and processed is binary digit where \( k = b = 2 \).

Theorem 2 indicates that any form of information in the physical (natural) and abstract (mental) worlds can be unified on the basis of binary data. This is the CI foundation of modern digital computers and NI.

The Layered Reference Model of the Brain

The LRMB (Wang et al., 2006) is developed to explain the fundamental cognitive mechanisms and processes of natural intelligence. Because a variety of life functions and cognitive processes have been identified in CI, psychology, cognitive science, brain science, and neurophilosophy, there is a need to organize all the recurrent cognitive processes in an integrated and coherent framework. The LRMB model explains the functional mechanisms and cognitive processes of natural intelligence that encompasses 37 cognitive processes at six layers known as the sensation, memory, perception, action, metacognitive, and higher cognitive layers from the bottom-up as shown in Figure 3. LRMB elicits the core and highly repetitive recurrent cognitive processes from a huge variety of life functions, which may shed light on the study of the fundamental mechanisms and interactions of complicated mental processes, particularly the relationships and interactions between the inherited and the acquired life functions as well as those of the subconscious and conscious cognitive processes.

The OAR Model of Information Representation in the Brain

Investigation into the cognitive models of information and knowledge representation in the brain is perceived to be one of the fundamental research areas that help to unveil the mechanisms of the brain. The Object-Attribute-Relation (OAR) model (Wang, 2006h; Wang et al., 2003) describes human memory, particularly the long-term memory, by using the relational metaphor, rather than the traditional container metaphor that used to be adopted in psychology, computing, and information science. The OAR model shows that human memory and knowledge are represented by relations, that is, connections of synapses between neurons, rather than by the neurons themselves as the traditional container metaphor described. The OAR model can be used to explain a wide range of human information processing mechanisms and cognitive processes.

The Cognitive Informatics Model of the Brain

The human brain and its information processing mechanisms are centred in CI. A cognitive informatics model of the brain is proposed in Wang and Wang (2006), which explains the natural intelligence via interactions between the inherent (subconscious) and acquired (conscious) life functions. The model demonstrates that memory is the foundation for any natural intelligence. Formalism in forms of mathematics, logic, and rigorous treatment is introduced into the study of cognitive and neural psychology and natural
informatics. Fundamental cognitive mechanisms of the brain, such as the architecture of the thinking engine, internal knowledge representation, long-term memory establishment, and roles of sleep in long-term memory development have been investigated (Wang & Wang, 2006).

**Natural Intelligence (NI)**

Natural Intelligence (NI) is the domain of CI. Software and computer systems are recognized as a subset of intelligent behaviors of human beings described by programmed instructive information (Wang, 2003b; Wang & Kinsner, 2006). The relationship between Artificial Intelligence (AI) and NI can be described by the following theorem.

**Theorem 3.** The law of compatible intelligent capability states that artificial intelligence (AI) is always a subset of the natural intelligence (NI), that is:

\[ AI \subseteq NI \]  

Theorem 3 indicates that AI is dominated by NI. Therefore, one should not expect a computer or a software system to solve a problem where humans cannot. In other words, no AI or computing system may be designed and/or implemented for a given problem where there is no solution being known by human beings.

**Neural Informatics (NeI)**

**Definition 5.** Neural Informatics (NeI) is a new interdisciplinary enquiry of the biological and physiological representation of information and knowledge in the brain at the neuron level and their abstract mathematical models (Wang, 2004; Wang & Wang, 2006).

NeI is a branch of CI, where memory is recognized as the foundation and platform of any natural or artificial intelligence (Wang & Wang, 2006).

**Definition 6.** The Cognitive Models of Memory (CMM) states that the architecture of human memory is parallel configured by the Sensory Buffer Memory (SBM), Short-Term Memory (STM), Long-Term Memory (LTM), and Action-Buffer Memory (ABM), that is:

\[ CMM = SBM \parallel STM \parallel LTM \parallel ABM \]  

where the ABM is newly identified in Wang and Wang (2006).

The major organ that accommodates memories in the brain is the cerebrum or the cerebral cortex. In particular, the association and premotor cortex in the frontal lobe, the temporal lobe, sensory cortex in the frontal lobe, visual cortex in the occipital lobe, primary motor cortex in the frontal lobe, supplementary motor area in the frontal lobe, and procedural memory in cerebellum (Wang & Wang, 2006).

The CMM model and the mapping of the four types of human memory onto the physiological organs in the brain reveal a set of fundamental mechanisms of NeI. The OAR model of information/knowledge representation described in the OAR model of information representation in the brain section provides a generic description of information/knowledge representation in the brain (Wang, 2006h; Wang et al., 2003).

The theories of CI and NeI explain a number of important questions in the study of NI. Enlightening conclusions derived in CI and NeI are such as: (a) LTM establishment is a subconscious process; (b) The long-term memory is established during sleeping; (c) The major mechanism for LTM establishment is by sleeping; (d) The general acquisition cycle of LTM is equal to or longer than 24 hours; (e) The mechanism of LTM establishment is to update the entire memory of information represented as an OAR model in the brain; and (f) Eye movement and dreams play an important
role in LTM creation. The latest development in CI and NeI has led to the determination of the magnificent and expected capacity of human memory as described in the Estimation of the Capacity of Human Memory section.

**Cognitive Informatics Laws of Software**

It is commonly conceived that software as an artifact of human creativity is not constrained by the laws and principles discovered in the physical world. However, it is unknown what constrains software. The new informatics metaphor proposed by the author in CI perceives software is a type of instructive and behavioral information. Based on this, it is asserted that software obeys the laws of informatics. A comprehensive set of 19 CI laws for software have been established in Wang (2006f), such as:

1. Abstraction
2. Generality
3. Cumulativeness
4. Dependency on cognition
5. Three-dimensional behavior space known as the object (O), space (S), and time (T)
6. Sharability
7. Dimensionless
8. Weightless
9. Transformability between I-M-E
10. Multiple representation forms
11. Multiple carrying media
12. Multiple transmission forms
13. Dependency on media
14. Dependency on energy
15. Wearless and time dependency
16. Conservation of entropy
17. Quality attributes of informatics
18. Susceptible to distortion
19. Scarcity

The informatics laws of software extend the knowledge on the fundamental laws and properties of software where the conventional product metaphor could not explain. Therefore, CI forms one of the foundations of software engineering and computing science.

**Mechanisms of Human Perception Processes**

**Definition 7.** *Perception* is a set of interpretive cognitive processes of the brain at the subconscious cognitive function layers that detects, relates, interprets, and searches internal cognitive information in the mind.

Perception may be considered as the *sixth sense* of human beings, which almost all cognitive life functions rely on. Perception is also an important cognitive function at the subconscious layers that determines personality. In other words, personality is a faculty of all subconscious life functions and experience cumulated via conscious life functions.

According to LRMB, the main cognitive processes at the perception layer are emotion, motivation, and attitude (Wang, 2005a). The relationship between the internal emotion, motivation, attitude, and the embodied external behaviors can be formally and quantitatively described by the *motivation/attitude-driven behavioral* (MADB) *model* (Wang & Wang, 2006), which demonstrates that complicated psychological and cognitive mental processes may be formally modeled and rigorously described by mathematical means (Wang, 2002b, 2003d, 2005c).

**The Cognitive Processes of Formal Inferences**

*Theoretical research* is predominately an inductive process, while *applied research* is mainly a deductive one. Both inference processes are based on the cognitive process and means of abstraction. *Abstraction* is a powerful means of philosophy and mathematics. It is also a preeminent trait of the human brain identified in CI studies (Wang,
All formal logical inferences and reasonings can only be carried out on the basis of abstract properties shared by a given set of objects under study.

**Definition 8.** *Abstraction* is a process to elicit a subset of objects that shares a common property from a given set of objects and to use the property to identify and distinguish the subset from the whole in order to facilitate reasoning.

Abstraction is a gifted capability of human beings. Abstraction is a basic cognitive process of the brain at the metacognitive layer according to LRMB (Wang et al., 2006). Only by abstraction can important theorems and laws about the objects under study be elicited and discovered from a great variety of phenomena and empirical observations in an area of inquiry.

**Definition 9.** *Inferences* are a formal cognitive process that reasons a possible causality from given premises based on known causal relations between a pair of cause and effect proven true by empirical arguments, theoretical inferences, or statistical regulations.

Formal inferences may be classified into the deductive, inductive, abductive, and analogical categories (Wang, 2005c). *Deduction* is a cognitive process by which a specific conclusion necessarily follows from a set of general premises. *Induction* is a cognitive process by which a general conclusion is drawn from a set of specific premises based on three designated samples in reasoning or experimental evidences. *Abduction* is a cognitive process by which an inference to the best explanation or most likely reason of an observation or event. *Analogy* is a cognitive process by which an inference about the similarity of the same relations holds between different domains or systems, and/or examines that if two things agree in certain respects, then they probably agree in others. A summary of the formal definitions of the five inference techniques is shown in Table 1.

For seeking generality and universal truth, either the objects or the relations can only be abstractly described and rigorously inferred by abstract models rather than real-world details.

**The Formal Knowledge System**

Mathematical thoughts (Jordan & Smith, 1997) provide a successful paradigm to organize and validate human knowledge, where once a truth or a theorem is established, it is true until the axioms or conditions that it stands for are changed or extended. A proven truth or theorem in mathematics does not need to be argued each time one uses it. This is the advantage and efficiency of formal knowledge in science and engineering. In other words, if any theory or conclusion may be argued from time-to-time based on a wiser idea or a trade-off, it is an empirical result rather than a formal one.

The Framework of Formal Knowledge (FFK) of mankind (Wang, 2006g) can be described as shown in Figure 5. An FFK is centered by a set of theories. A *theory* is a statement of how and why certain objects, facts, or truths are related. All objects in nature and their relations are constrained by invariable laws, no matter if one observed them or not at any given time. An *empirical truth* is a truth based on or verifiable by observation, experiment, or experience. A *theoretical proposition* is an assertion based on formal theories or logical reasoning. Theoretical knowledge is a formalization of generic truth and proven abstracted empirical knowledge. Theoretical knowledge may be easier to acquire when it exists. However, empirical knowledge is very difficult to be gained without hands-on practice.

According to the FFK model, an immature discipline of science and engineering is characterized by its body of knowledge not being formalized. Instead of a set of proven theories, the immature disciplines document a large set of
observed facts, phenomena, and their possible or partially working explanations and hypotheses. In such disciplines, researchers and practitioners might be able to argue every informal conclusion documented in natural languages from time-to-time probably for hundreds of years, until it is formally described in mathematical forms and proved rigorously.

The disciplines of mathematics and physics are successful paradigms that adopt the FFK formal knowledge system. The key advantages of the formal knowledge system are its stability and efficiency. The former is a property of the formal knowledge that once it is established and formally proved, users who refers to it will no longer need to reexamine or reprove it. The latter is a property of formal knowledge that is exclusively true or false that saves everybody’s time from arguing a proven theory.

**DENOTATIONAL MATHEMATICS FOR CI**

The history of sciences and engineering shows that new problems require new forms of mathematics. CI is a new discipline, and the problems in it require new mathematical means that are descriptive and precise in expressing and denoting human and system actions and behaviors. Conventional analytic mathematics are unable to solve the fundamental problems inherited in CI and related disciplines such as neuroscience, psychology, philosophy, computing, software engineering, and knowledge engineering. Therefore, denotational mathematical structures and means (Wang, 2006c) beyond mathematical logic are yet to be sought.

Although there are various ways to express facts, objects, notions, relations, actions, and behaviors in natural languages, it is found in CI that human and system behaviors may be classified into three basic categories known as to be, to have, and to do. All mathematical means and forms, in general, are an abstract and formal description of these three categories of expressibility and their rules. Taking this view, mathematical logic may be perceived as the abstract means for describing “to be,” set theory describing “to have,” and algebras, particularly process algebra, describing “to do.”

The Theoretical Framework of Cognitive Informatics

Theorem 4. The utility of mathematics is the means and rules to express thought rigorously and generically at a higher level of abstraction.

Three types of new mathematics, Concept Algebra (CA), Real-Time Process Algebra (RTPA), and System Algebra (SA), are created in CI to enable rigorous treatment of knowledge representation and manipulation in a formal and coherent framework. The three new structures of contemporary mathematics have extended the abstract objects under study in mathematics from basic mathematical entities of numbers and sets to a higher level, that is, concepts, behavioral processes, and systems. A wide range of applications of the denotational mathematics in the context of CI has been identified (Wang, 2002b, 2006d, e).

Concept Algebra

A concept is a cognitive unit (Ganter & Wille, 1999; Quillian, 1968; Wang, 2006e) by which the meanings and semantics of a real-world or an abstract entity may be represented and embodied based on the OAR model.

Definition 10. An abstract concept \( c \) is a 5-tuple, that is:

\[
c \triangleq (O, A, R^e, R^r, R^\prime)
\]  

where

- \( O \) is a nonempty set of object of the concept, \( O = \{o_1, o_2, ..., o_m\} \subseteq U \), where \( \mathcal{P}U \) denotes a power set of \( U \).
- \( A \) is a nonempty set of attributes, \( A = \{a_1, a_2, ..., a_n\} \subseteq \mathcal{P}M \).
• \( R^c \subseteq O \times A \) is a set of internal relations.
• \( R^i \subseteq C' \times C \) is a set of input relations, where \( C' \) is a set of external concepts.
• \( R^o \subseteq C \times C' \) is a set of output relations.

A structural concept model of \( c = (O, A, R^c, R^i, R^o) \) can be illustrated in Figure 6, where \( c, A, O, \) and \( R, R = \{R^c, R^i, R^o\} \), denote the concept, its attributes, objects, and internal/external relations, respectively.

**Definition 11.** Concept algebra is a new mathematical structure for the formal treatment of abstract concepts and their algebraic relations, operations, and associative rules for composing complex concepts and knowledge (Wang, 2006e).

Concept algebra deals with the algebraic relations and associational rules of abstract concepts. The associations of concepts form a foundation to denote complicated relations between concepts in knowledge representation. The associations among concepts can be classified into nine categories, such as inheritance, extension, tailoring, substitute, composition, decomposition, aggregation, specification, and instantiation as shown in Figure 6 and Table 2 (Wang, 2006e). In Figure 6, \( R = \{R^c, R^i, R^o\} \), and all nine associations describe composing rules among concepts, except instantiation that is a relation between a concept and a specific object.

**Definition 12.** A generic knowledge \( K \) is an \( n \)-nary relation \( R_k \) among a set of \( n \) multiple concepts in \( C \), that is:

\[
K = R_k : (\bigcup_{i=1}^{n} C_i) \rightarrow C
\]

where \( \bigcup_{i=1}^{n} C_i = C \), and \( R_k \in \mathcal{R} = \{\Rightarrow, \Rightarrow, \Rightarrow, \Rightarrow, \Rightarrow, \Rightarrow, \Rightarrow, \Rightarrow, \Rightarrow\} \).

In Definition 12, the relation \( R_k \) is one of the concept operations in CA as defined in Table 2 (Wang, 2006e) that serves as the knowledge composing rules.

**Definition 13.** A concept network \( CN \) is a hierarchical network of concepts interlinked by the set of nine associations \( \mathcal{R} \) defined in CA, that is:

---

**Figure 6.** The nine concept association operations as knowledge composing rules

![Diagram showing the nine concept association operations as knowledge composing rules.](image)
The Theoretical Framework of Cognitive Informatics

\[ CN = R \sum_{i,j}^{n} C_i \rightarrow \sum_{i,j}^{n} C_j \]  

(9)

where \( R \in \mathbb{R} \).

Because the relations between concepts are transitive, the generic topology of knowledge is a hierarchical concept network. The advantages of the hierarchical knowledge architecture \( K \) in the form of concept networks are as follows:

(a) **Dynamic**: The knowledge networks may be updated dynamically along with information acquisition and learning without destructing the existing concept nodes and relational links.

(b) **Evolvable**: The knowledge networks may grow adaptively without changing the overall and existing structure of the hierarchical network.

A summary of the algebraic relations and operations of concepts defined in CA are provided in Table 2.

**Real-Time Process Algebra (RTPA)**

A key metaphor in system modeling, specification, and description is that a software system can be perceived and described as the composition of a set of interacting processes. Hoare (1985), Milner (1989), and others developed various algebraic approaches to represent communicating and concurrent systems, known as process algebra. A **process algebra** is a set of formal notations and rules for describing algebraic relations of software processes. **Real-Time Process Algebra** (Wang, 2002b, 2005b) extends process algebra to time/event, architecture, and system dispatching manipulations in order to formally describe and specify architectures and behaviors of software systems. A process in RTPA is a computational operation that transforms a system from a state to another by changing its inputs, outputs, and/or internal variables. A process can be a single metaprocess or a complex process formed by using the process combination rules of RTPA known as process relations.

**Definition 14. Real-Time Process Algebra** is a set of formal notations and rules for describing algebraic and real-time relations of software processes.

RTPA models 17 metaprocesses and 17 process relations. A metaprocess is an elementary and primary process that serves as a common and basic building block for a software system. Complex processes can be derived from metaprocesses by a set of process relations that serves as process combinatory rules. Detailed semantics of RTPA may be referred to in Wang (2002b).

Program modeling is on coordination of computational behaviors with given data objects. Behavioral or instructive knowledge can be modeled by RTPA. A **generic program model** can be described by a formal treatment of statements, processes, and complex processes from the bottom-up in the program hierarchy.

**Definition 15.** A process \( P \) is a composed listing and a logical combination of \( n \) metatstatements \( p_i \) and \( p_j \), \( 1 \leq i < n, 1 < j \leq m = n+1 \), according to certain composing relations \( r_{ij} \), that is:

\[
P = \bigcap_{i=1}^{n} (p_i \rightarrow r_{ij} p_j), j = i + 1
\]

\[
= (\ldots (((p_i) \rightarrow r_{11} p_1) \rightarrow r_{23} p_3) \ldots r_{n-1,n} p_n)
\]

(10)

where the big-R notation (Wang, 2002b, 2006i) is adopted to describes the nature of processes as the building blocks of programs.

**Definition 16.** A program \( \Psi \) is a composition of a finite set of \( m \) processes according to the time-, event-, and interrupt-based process dispatching rules, that is:

\[
\Psi = \bigcap_{k=1}^{m} (@ e_k \rightarrow P_k)
\]

(11)

Equations 9.1 and 10.1 indicate that a program is an **embedded relational algebraic** entity. A
statement $p$ in a program is an instantiation of a metainstruction of a programming language that executes a basic unit of coherent function and leads to a predictable behavior.

**Theorem 5.** The embedded relational model (ERM) states that a software system or a program $\mathbb{P}$ is a set of complex embedded relational processes, in which all previous processes of a given process form the context of the current process, that is:

$$\mathbb{P} = \mathbb{R}[\langle e_i \rightharpoonup p_j \rangle]_{i=1}^{m}$$

(12)

ERM presented in Theorem 5 provides a unified mathematical model of programs (Wang, 2006a) for the first time, which reveals that a program is a finite and nonempty set of embedded binary relations between a current statement and all previous ones that formed the semantic context or environment of computing.

**Definition 17.** A metaprocess is the most basic and elementary processes in computing that cannot be broken up further. The set of metaprocesses $P$ encompasses 17 fundamental primitive operations in computing as follows:

$$P = \{:=, &, \Rightarrow, \Leftrightarrow, <, |>, |<, |<, \triangle, \downarrow, \!\!, \otimes, , \$\}$$

(13)

**Definition 18.** A process relation is a composing rule for constructing complex processes by using the metaprocesses. The process relations $R$ of RTPA are a set of 17 composing operations and rules to build larger architectural components and complex system behaviors using the metaprocesses, that is:

$$R = \{\rightarrow, \cap, |, \ldots, \emptyset, \cup, \Rightarrow, \|, \|\}$$

(14)

The definitions, syntaxes, and formal semantics of each of the metaprocesses and process relations may be referred to RTPA (Wang, 2002b, 2006f). A complex process and a program can be derived from the metaprocesses by the set of algebraic process relations. Therefore, a program is a set of embedded relational processes as described in Theorem 5.

A summary of the metaprocesses and their algebraic operations in RTPA are provided in Table 2.

**System Algebra (SA)**

Systems are the most complicated entities and phenomena in the physical, information, and social worlds across all science and engineering disciplines (Klir, 1992; von Bertalanffy, 1952; Wang, 2006d). Systems are needed because the physical and/or cognitive power of an individual component or person is not enough to carry out a work or solving a problem. An abstract system is a collection of coherent and interactive entities that has stable functions and clear boundary with external environment. An abstract system forms the generic model of various real world systems and represents the most common characteristics and properties of them.

**Definition 19.** System algebra is a new abstract mathematical structure that provides an algebraic treatment of abstract systems as well as their relations and operational rules for forming complex systems (Wang, 2006d).

Abstract systems can be classified into two categories known as the closed and open systems. Most practical and useful systems in nature are open systems in which there are interactions between the system and its environment. However, for understanding easily, the closed system is introduced first.
Definition 20. A closed system is a 4-tuple, that is:
\[ S = (C, R, B, \Omega) \] (15)

where
- \( C \) is a nonempty set of components of the system, \( C = \{c_1, c_2, \ldots, c_n\} \).
- \( R \) is a nonempty set of relations between pairs of the components in the system, \( R = \{r_1, r_2, \ldots, r_m\}, R \subseteq C \times C \).
- \( B \) is a set of behaviors (or functions), \( B = \{b_1, b_2, \ldots, b_p\} \).
- \( \Omega \) is a set of constraints on the memberships of components, the conditions of relations, and the scopes of behaviors, \( \Omega = \{\omega_1, \omega_2, \ldots, \omega_q\} \).

Most practical systems in the real world are not closed. That is, they need to interact with the external world known as the environment \( \Theta \) in order to exchange energy, matter, and/or information. Such systems are called open systems. Typical interactions between an open system and the environment are inputs and outputs.

Definition 21. An open system \( S \) is a 7-tuple, that is:
\[ S = (C, R, B, \Omega, \Theta) \]
\[ = (C, R^c, R^i, R^o, B, \Omega, \Theta) \] (16)

where the extensions of entities beyond the closed system are as follows:
- \( \Theta \) is the environment of \( S \) with a nonempty set of components \( C_\Theta \) outside \( C \).
- \( R^c \subseteq C \times C \) is a set of internal relations.
- \( R^i \subseteq C_\Theta \times C \) is a set of external input relations.
- \( R^o \subseteq C \times C_\Theta \) is a set of external output relations.

An open system \( S=(C, R^c, R^i, R^o, B, \Omega, \Theta) \) can be illustrated in Figure 7 (Wang, 2006d).

Theorem 6. The equivalence between open and closed systems states that an open system \( S \) is equivalent to a closed system \( \hat{S} \), or vice versa, when its environment or is conjoined, respectively, that is:
\[ \left\{ \begin{array}{l} \hat{S} = S \sqcup \Theta_S \\ S = \hat{S} \sqcup \Theta_{\hat{S}} \end{array} \right. \] (17)
According to Theorem 6, any subsystem of a closed system $\hat{S}$ is an open system $S$. That is, any supersystem $S$ of a given set of $n$ open systems $S_k$, plus their environments $\Theta_k$, $1 \leq k \leq n$, is a closed system. The algebraic relations and operations of systems in SA are summarized in Table 2.

**Theorem 7.** The Wang’s first law of system science, system fusion, states that system conjunction or composition between two systems $S_1$ and $S_2$ creates new relations $\Delta R_{12}$ and/or new behaviors (functions) $\Delta B_{12}$ that are solely a property of the new supersystem $S$ determined by the sizes of the two intersected component sets $\#(C_1)$ and $\#(C_2)$, that is:

$$
\Delta R_{12} = \#(R) - (\#(R_1) + \#(R_2)) = (\#(C_1 + C_2))^2 - (\#(C_1))^2 - (\#(C_2))^2 = 2 \#(C_1) \cdot \#(C_2)
$$

The discovery in Theorem 7 reveals that the mathematical explanation of system utilities is the newly gained relations $\Delta R_{12}$ and/or behaviors (functions) $\Delta B_{12}$ during the conjunction of two systems or subsystems. The empirical awareness of this key system property has been intuitively or qualitatively observed for centuries. However, Theorem 7 is the first rigorous explanation of the mechanism of system gains during system conjunctions and compositions. According to Theorem 7, the maximum incremental or system gain equals to the number of by-directly interconnection between all components in both $S_1$ and $S_2$, that is, $2 \#(C_1) \cdot \#(C_2)$.

**Theorem 8.** The Wang’s 2nd law of system science, the maximum system gain, states that work done by a system is always larger than any of its components, but is less than or is equal to the sum of those of its components, that is:

$$
W(S) \leq \sum_{i=1}^{n} W(e_i), \quad \eta \leq 1
$$

$$
W(S) > \max(W(e_i)), \quad e_i \in E_S
$$

There was a myth on an ideal system in conventional systems theory that supposes the work done by the ideal system $W(S)$ may be greater than the sum of all its components $W(e_i)$, that is:

$$
W(S) \geq \sum_{i=1}^{n} W(e_i)
$$

According to Theorems 7 and 8, the ideal system utility is impossible to achieve.

A summary of the algebraic operations and their notations in CA, RTPA, and SA is provided in Table 2. Details may be referred to in Wang (2006d, g).

**APPLICATIONS OF CI**

The last two sections have reviewed the latest development of fundamental researches in CI, particularly its theoretical framework and descriptive mathematics. A wide range of applications of CI has been identified in multidisciplinary and transdisciplinary areas, such as: (1) The architecture of future generation computers; (2) Estimation the capacity of human memory; (3) Autonomic computing; (4) Cognitive properties of information, data, knowledge, and skills in knowledge engineering; (5) Simulation of human cognitive behaviors using descriptive mathematics; (6) Agent systems; (7) CI foundations of software engineering; (8) Deductive semantics of software; and (9) Cognitive complexity of software.

**The Architecture of Future Generation Computers**

Conventional machines are invented to extend human physical capability, while modern information processing machines, such as computers, communication networks, and robots, are developed for extending human intelligence, memory, and the capacity for information processing (Wang, 2004). Recent advances in CI provide formal description of an entire set of cognitive processes of the brain (Wang et al.,

2006). The fundamental research in CI also creates an enriched set of contemporary denotational mathematics (Wang, 2006c), for dealing with the extremely complicated objects and problems in natural intelligence, neural informatics, and knowledge manipulation.

The theory and philosophy behind the next generation computers and computing methodologies are CI (Wang, 2003b, 2004). It is commonly believed that the future-generation computers, known as the cognitive computers, will adopt non-von Neumann (von Neumann, 1946) architectures. The key requirements for implementing a conventional stored-program controlled computer are the generalization of common computing architectures and the computer is able to interpret the data loaded in memory as computing instructions. These are the essences of stored-program...
controlled computers known as the von Neumann (1946) architecture. Von Neumann elicited five fundamental and essential components to implement general-purpose programmable digital computers in order to embody the concept of stored-program-controlled computers.

**Definition 22.** A von Neumann Architecture (VNA) of computers is a 5-tuple that consists of the components: (a) the arithmetic-logic unit (ALU), (b) the control unit (CU) with a program counter (PC), (c) a memory (M), (d) a set of input/output (I/O) devices, and (e) a bus (B) that provides the data path between these components, that is:

$$VNA \triangleq (ALU, CU, M, I/O, B)$$

**Definition 23.** Conventional computers with VNA are aimed at stored-program-controlled data processing based on mathematical logic and Boolean algebra.

A VNA computer is centric by the bus and characterized by the all purpose memory for both data and instructions. A VNA machine is an extended Turing machine (TM), where the power and functionality of all components of TM including the control unit (with wired instructions), the tape (memory), and the head of I/O, are greatly enhanced and extended with more powerful instructions and I/O capacity.

**Definition 24.** A Wang Architecture (WA) of computers, known as the Cognitive Machine as shown in Figure 8, is a parallel structure encompassing an Inference Engine (IE) and a Perception Engine (PE) (Wang, 2006b, g), that is:

$$WA \triangleq (IE \parallel PE)$$

$$= ( KMU// The knowledge manipulation unit$$

$$\parallel BMU// The behavior manipulation unit$$

$$\parallel EMU // The experience manipulation unit$$

$$\parallel SMU// The skill manipulation unit$$

$$\parallel ( BPU // The behavior perception unit$$

$$\parallel EPU // The experience perception unit$$

$$)$$

$$CM = IE \parallel PE$$

$$= ( KMU// The knowledge manipulation unit$$

$$\parallel BMU// The behavior manipulation unit$$

$$\parallel EMU // The experience manipulation unit$$

$$\parallel SMU// The skill manipulation unit$$

$$\parallel ( BPU // The behavior perception unit$$

$$\parallel EPU // The experience perception unit$$

$$)$$

(21)
As shown in Figure 8 and Equation 21, WA computers are not centered by a CPU for data manipulation as the VNA computers do. The WA computers are centered by the concurrent IE and PE for cognitive learning and autonomic perception based on abstract concept inferences and empirical stimuli perception. The IE is designed for concept/knowledge manipulation according to concept algebra (Wang, 2006e), particularly the nine concept operations for knowledge acquisition, creation, and manipulation. The PE is designed for feeling and perception processing according to RTPA (Wang, 2002b) and the formally described cognitive process models of the perception layers as defined in the LRMB model (Wang et al., 2006).

**Definition 25.** Cognitive computers with WA are aimed at cognitive and perceptive concept/knowledge processing based on contemporary denotational mathematics, that is, CA, RTPA, and SA.

As that of mathematical logic and Boolean algebra are the mathematical foundations of VNA computers. The mathematical foundations of WA computers are based on denotational mathematics (Wang, 2006b, c). As described in the LRMB reference model (Wang et al., 2006), since all the 37 fundamental cognitive processes of human brains can be formally described in CA and RTPA (Wang, 2002b, 2006e). In other words, they are simulatable and executable by the WA-based cognitive computers.

**Estimation of the Capacity of Human Memory**

Despite the fact that the number of neurons in the brain has been identified in cognitive and neural sciences, the magnitude of human memory capacity is still unknown. According to the OAR model, a recent discovery in CI is that the upper bound of memory capacity of the human brain is in the order of $10^{8.432}$ bits (Wang et al., 2003). The determination of the magnitude of human memory capacity is not only theoretically significant in CI, but also practically useful to unveil the human potential, as well as the gaps between the natural and machine intelligence. This result indicates that the next generation computer memory systems may be built according to the OAR model rather than the traditional container metaphor, because the former is more powerful, flexible, and efficient to generate a tremendous memory capacity by using limited number of neurons in the brain or hardware cells in the next generation computers.

**Autonomic Computing**

The approaches to implement intelligent systems can be classified into those of biological organisms, silicon automata, and computing systems. Based on CI studies, *autonomic computing* (Wang, 2004) is proposed as a new and advanced computing technique built upon the routine, algorithmic, and adaptive systems as shown in Table 3.

The approaches to computing can be classified into two categories known as imperative and autonomic computing. Corresponding to these,

---

**Table 3. Classification of computing systems**

</tr>
</tbody>
</table>
computing systems may be implemented as imperative or autonomic computing systems.

**Definition 26.** An imperative computing system is a passive system that implements deterministic, context-free, and stored-program controlled behaviors.

**Definition 27.** An autonomic computing system is an intelligent system that autonomously carries out robotic and interactive actions based on goal- and event-driven mechanisms.

The imperative computing system is a traditional passive system that implements deterministic, context-free, and stored-program controlled behaviors, where a behavior is defined as a set of observable actions of a given computing system. The autonomic computing system is an active system that implements nondeterministic, context-dependent, and adaptive behaviors, which do not rely on instructive and procedural information, but are dependent on internal status and willingness that formed by long-term historical events and current rational or emotional goals.

The first three categories of computing techniques as shown in Table 3 are imperative. In contrast, the autonomic computing systems are an active system that implements nondeterministic, context-sensitive, and adaptive behaviors. Autonomic computing does not rely on imperative and procedural instructions, but are dependent on perceptions and inferences based on internal goals as revealed in CI.

### Cognitive Properties of Knowledge

Almost all modern disciplines of science and engineering deal with information and knowledge. According to CI theories, cognitive information may be classified into four categories known as knowledge, behaviors, experience, and skills as shown in Table 4.

**Definition 28.** The taxonomy of cognitive information is determined by its types of inputs and outputs to and from the brain during learning and information processing, where both inputs and outputs can be either abstract information (concept) or empirical information (actions).

It is noteworthy that the approaches to acquire knowledge/behaviors and experience/skills are fundamentally different. The former may be obtained either directly based on hands-on activities or indirectly by reading, while the latter can never be acquired indirectly.

According to Table 4, the following important conclusions on information manipulation and learning for both human and machine systems can be derived.

**Theorem 9.** The principle of information acquisition states that there are four sufficient categories of learning known as those of knowledge, behaviors, experience, and skills.

Theorem 9 indicates that learning theories and their implementation in autonomic and intelligent systems should study all four categories of

### Table 4. Types of cognitive information

</table>

51
cognitive information acquisitions, particularly behaviors, experience, and skills rather than only focusing on knowledge.

**Corollary 3.** All the four categories of information can be acquired directly by an individual.

**Corollary 4.** Knowledge and behaviors can be learnt indirectly by inputting abstract information, while experience and skills must be learned directly by hands-on or empirical actions.

The above theory of CI lays an important foundation for learning theories and pedagogy (Wang, 2004, 2006e). Based on the fundamental work, the IE and PE of cognitive computers working as a virtual brain can be implemented on WA-based cognitive computers and be simulated on VNA-based conventional computers.

**Simulation of Human Cognitive Behaviors using the Contemporary Mathematics**

The contemporary denotational mathematics as described in The Denotational Mathematics for CI section, particularly CA and RTPA, may be used to simulate the cognitive processes of the brain as modeled in LRMB (Wang et al., 2006). Most of the 37 cognitive processes identified in LRMB, such as the learning (Wang, 2006c), reasoning (Wang, 2006b), decision making (Wang et al., 2004), and comprehension (Wang & Gafurov, 2003) processes, have been rigorously modeled and described in RTPA and CA. Based on the fundamental work, the inference engineering and perception engine of a virtual brain can be implemented on cognitive computers or be simulated on conventional computers. In the former case, a working prototype of a fully autonomic computer will be realized on the basis of CI theories.

**Agent Systems**

**Definition 29.** A *software agent* is an intelligent software system that autonomously carries out robotic and interactive applications based on goal-driven mechanisms (Wang, 2003c).

Because a software agent may be perceived as an application-specific virtual brain (see Theorem 3), behaviors of an agent are mirrored human behaviors. The fundamental characteristics of agent-based systems are autonomic computing, goal-driven action-generation, knowledge-based machine learning. In recent CI research, perceptivity is recognized as the sixth sense that serves the brain as the thinking engine and the kernel of the natural intelligence. Perceptivity implements self-consciousness inside the abstract memories of the brain. Almost all cognitive life functions rely on perceptivity such as consciousness, memory searching, motivation, willingness, goal setting, emotion, sense of spatiality, and sense of motion. The brain may be stimulated by external and internal information, which can be classified as willingness-driven (internal events such as goals, motivation, and emotions), event-driven (external events), and time-driven (mainly external events triggered by an external clock). Unlike a computer, the brain works in two approaches: the internal willingness-driven processes, and the external event- and time-driven processes. The external information and events are the major sources that drive the brain, particularly for conscious life functions.

Recent research in CI reveals that the foundations of agent technologies and autonomic computing are CI, particularly goal-driven action generation techniques (Wang, 2003c). The LRMB model (Wang et al., 2006) described in the Layered Reference Model of the Brain section may be used as a reference model for agent-based technologies. This is a fundamental view toward
The formal description and modeling of architectures and behaviors of agent systems, which are created to do something repeatable in context, to extend human capability, reachability, and/or memory capacity. It is found that both human and software behaviors can be described by a 3-dimensional representative model comprising action, time, and space. For agent system behaviors, the three dimensions are known as mathematical operations, event/process timing, and memory manipulation (Wang, 2006g). The 3-D behavioral space of agents can be formally described by RTPA that serves as an expressive mathematical means for describing thoughts and notions of dynamic system behaviors as a series of actions and cognitive processes.

**CI Foundations of Software Engineering**

Software is an intellectual artifact and a kind of instructive information that provides a solution for a repeatable computer application, which enables existing tasks to be done easier, faster, and smarter, or which provides innovative applications for the industries and daily life. Large-scale software systems are highly complicated systems that have never been handled or experienced precedent by mankind.

The fundamental cognitive characteristics of software engineering have been identified as follows (Wang, 2006g):

- The inherent complexity and diversity
- The difficulty of establishing and stabilizing requirements
- The changeability or malleability of system behavior
- The abstraction and intangibility of software products
- The requirement of varying problem domain knowledge
- The non-deterministic and polysolvability in design
- The polyglotics and polymorphism in implementation
- The dependability of interactions among software, hardware, and human beings

The above list forms a set of fundamental constraints for software engineering, identified as the cognitive constraints of intangibility, complexity, indeterminacy, diversity, polymorphism, inexpressiveness, inexplicit embodiment, and unquantifiable quality measures (Wang, 2006g).

A set of psychological requirements for software engineers has been identified, such as:

(a) Abstract-level thinking; (b) Imagination of dynamic behaviors with static descriptions; (c) Organization capability; (d) Cooperative attitude in team work; (e) Long-period focus of attentions; (f) Preciseness; (g) Reliability; and (h) Expressive capability in communication.

**Deductive Semantics of Software**

Deduction is a reasoning process that discovers new knowledge or derives a specific conclusion based on generic premises such as abstract rules or principles. In order to provide an algebraic treatment of the semantics of program and human cognitive processes, a new type of formal semantics known as deductive semantics is developed (Wang, 2006f, g).

**Definition 30.** Deductive semantics is a formal semantics that deduces the semantics of a program from a generic abstract semantic function to the concrete semantics, which are embodied onto the changes of status of a finite set of variables constituting the semantic environment of computing (Wang, 2006g).

**Theorem 10.** The semantics of a statement \( p, \Theta(p) \) on a given semantic environment \( \Theta \) in deductive semantics is a double partial differential of the semantic function, \( f_{\Theta(p)}(p) = f_{\Theta}(p) \), on the sets of variables \( S \) and executing steps \( T \), that is:
Theoretical Framework of Cognitive Informatics

\[ \theta (p) = \frac{\partial^2}{\partial t \partial s} f_s (p) = \frac{\partial^2}{\partial t \partial s} v_s (t, s) \]

\[ = R \sum_{i=0}^{\#T(p)} R \sum_{j=1}^{\#S(p)} v_p (t_i, s_j) \]

\[ = R \sum_{i=0}^{\#T(p)} R \sum_{j=1}^{\#S(p)} v_p (t_i, s_j) \]

\[ = \left( \begin{array}{cccc} t_0 & s_1 & s_2 & \cdots & s_m \\ v_{01} & v_{02} & \cdots & v_{0m} \\ t_1 & s_1 & s_2 & \cdots & s_m \\ v_{11} & v_{12} & \cdots & v_{1m} \end{array} \right) \]  

(22)

where \( t \) denotes the discrete time immediately before and after the execution of \( p \) during \( (t_0, t_1] \), and \( \# \) is the cardinal calculus that counts the number of elements in a given set, that is \( n = \#T(p) \) and \( m = \#S(p) \).

The first partial differential in Equation 22 selects all related variable \( S(p) \) of the statement \( p \) from \( \Theta \). The second partial differential selects a set of discrete steps of \( p \)’s execution \( T(p) \) from \( \Theta \). According to Theorem 10, the semantics of a statement can be reduced onto a semantic function that results in a 2-D matrix with the changes of values for all variables over time along program execution.

Deductive semantics perceives that the carriers of software semantics are a finite set of variables declared in a given program. Therefore, software semantics can be reduced onto the changes of values of these variables. The deductive mathematical models of semantics and the semantic environment at various composing levels of systems are formally described. Properties of software semantics and relationships between the software behavioral space and the semantic environment are discussed. Deductive semantics is applied in the formal definitions and explanations of the semantic rules of a comprehensive set of software static and dynamic behaviors as modeled in RTPA. Deductive semantics can be used to define abstract and concrete semantics of software and cognitive systems, and facilitate software comprehension and recognition by semantic analyses.

Cognitive Complexity of Software

The estimation and measurement of functional complexity of software are an age-long problem in software engineering. The cognitive complexity of software (Wang, 2006) is a new measurement for cross-platform analysis of complexities, sizes, and comprehension effort of software specifications and implementations in the phases of design, implementation, and maintenance in software engineering. This work reveals that the cognitive complexity of software is a product of its architectural and operational complexities on the basis of deductive semantics and the abstract system theory. Ten fundamental basic control structures (BCSs) are elicited from software architectural/behavioral specifications and descriptions. The cognitive weights of those BCSs are derived and calibrated via a series of psychological experiments. Based on this work, the cognitive complexity of software systems can be rigorously and accurately measured and analyzed. Comparative case studies demonstrate that the cognitive complexity is highly distinguishable in software functional complexity and size measurement in software engineering.

On the basis of the ERM model described in Theorem 5 and the deductive semantics of software presented in The deductive semantics of software section, the finding on the cognitive complexity of software is obtained as follows.

**Theorem 11.** The sum of the cognitive weights of all \( r_{ij} \); \( w(r_{ij}) \), in the ERM model determines the operational complexity of a software system \( C_{op} \), that is:

\[ C_{op} = \sum_{i=1}^{n} w(r_{ij}), j = i + 1 \]  

(23)

A set of psychological experiments has been carried out in undergraduate and graduate classes in software engineering. Based on 126 experiment results, the equivalent cognitive weights of the
The Theoretical Framework of Cognitive Informatics

10 fundamental BCSs are statistically calibrated as summarized in Table 5 (Wang, 2006j), where the relative cognitive weight of the sequential structures is assumed one, that is, \( w_i = 1 \).

According to deductive semantics, the complexity of a software system, or its semantic space, is determined not only by the number of operations, but also by the number of data objects.

**Theorem 12.** The cognitive complexity \( C_c(S) \) of a software system \( S \) is a product of the operational complexity \( C_{op}(S) \) and the architectural complexity \( C_a(S) \), that is:

\[
C_c(S) = C_{op}(S) \cdot C_a(S)
\]

Based on Theorem 11, the cognitive complexities of four typical software components (Wang, 2006j) have been comparatively analyzes as summarized in Table 6. For enabling comparative analyses, data based on existing complexity measures, such as time, cyclomatic, and symbolic (LOC) complexities, are also contrasted in Table 6.

Observing Table 6 it can be seen that the first three traditional measurements cannot actually reflect the real complexity of software systems in software design, representation, cognition, comprehension, and maintenance. It is found that (a) Although four example systems are with similar symbolic complexities, their operational and functional complexities are greatly different. This indicates that the symbolic complexity cannot be used to represent the operational or functional complexity of software systems. (b) The symbolic complexity (LOC) does not represent the throughput or the input size of problems. (c) The time complexity does not work well for a system where there are no loops and dominate operations, because in theory that all statements

in linear structures are treated as zero in this measure no matter how long they are. In addition, time complexity cannot distinguish the real complexities of systems with the same asymptotic function, such as in Case 2 (IBS (b)) and Case 3 (Maxfinder). (d) The cognitive complexity is an ideal measure of software functional complexities and sizes, because it represents the real semantic complexity by integrating both the operational and architectural complexities in a coherent measure. For example, the difference between IBS(a) and IBS(b) can be successfully captured by the cognitive complexity. However, the symbolic and cyclomatic complexities cannot identify the functional differences very well.

**CONCLUSIONS**

This article has presented an intensive survey of the recent advances and groundbreaking studies in Cognitive informatics, particularly its theoretical framework, denotational mathematics, and main application areas. CI has been described as a new discipline that studies the natural intelligence and internal information processing mechanisms of the brain, as well as processes involved in perception and cognition. CI is a new frontier across disciplines of computing, software engineering, cognitive sciences, neuropsychology, brain sciences, and philosophy in recent years. It has been recognized that many fundamental issues in knowledge and software engineering are based on the deeper understanding of the mechanisms of human information processing and cognitive processes.

A coherent set of theories for CI has been described in this article, such as the Information-Matter-Energy model, Layered Reference Model of the Brain, the OAR model of information representation, Natural Intelligence vs. Artificial Intelligence, Autonomic Computing vs. imperative computing, CI laws of software, mechanisms of human perception processes, the cognitive processes of formal inferences, and the formal knowledge system. Three contemporary mathematical means have been created in CI known as the denotational mathematics. Within the new forms of denotational mathematical means for CI, Concept Algebra has been designed to deal with the new abstract mathematical structure of concepts and their representation and manipulation in learning and knowledge engineering. Real-Time Process Algebra has been developed as an expressive, easy-to-comprehend, and language-independent notation system, and a specification and refinement method for software system behaviors description and specification. System Algebra has been created to the rigorous treatment of abstract systems and their algebraic relations and operations.

A wide range of applications of CI has been identified in multidisciplinary and transdisciplinary areas, such as the architecture of future generation computers, estimation the capacity of human memory, autonomic computing, cognitive properties of information, data, knowledge,
The Theoretical Framework of Cognitive Informatics

and skills in knowledge engineering, simulation of human cognitive behaviors using descriptive mathematics, agent systems, CI foundations of software engineering, deductive semantics of software, and cognitive complexity of software systems.

Chapter 1.5
Human Factors in Public Information Systems

INTRODUCTION

News reports do not frequently mention many problems or accidents caused by human error. The specialty of human factors seeks to avoid human error by making certain that computers and all other equipment are designed to be easy to understand and use; costly human errors are thus minimised. This article provides a basic overview of the subject of human factors as it pertains to problem and error avoidance in computerised public information systems. When computer/system design does not adequately consider human capability, the performance of the computer/system and the user will be below desired levels.

BACKGROUND: HUMAN FACTORS, THE DISCIPLINE

Human factors has helped to make information systems less costly and easier to use. Some background on this discipline will help to show the relationship it has with information systems.

Human factors is the science of the relationships between humans, their activities, and the context in which those activities take place. The specialty of human factors came into being during WWII when it was found that the sophisticated equipment being designed did not perform as expected; there was a strong and immediate need to understand why many humans were unable to effectively use equipment and/or systems. Teams of researchers learned that the design strategies...
used did not consider human performance limitations—for example, some designs presented too much information at the same time or in the wrong order for humans to be able to successfully operate controls. Or, the arrangement of controls made them difficult to reach quickly and easily. From this discovery came the concept that human users, their work activities, and the contexts of the activities had to be thought of as different parts of a whole system and that each depends upon the other for successful operation (Bailey, 1996).

After WWII the discipline of human factors became a specialised knowledge area as it became apparent that the human element of any system had to be considered if the capabilities of new technologies were to be efficiently exploited. The older strategy of modifying designs over a long period of time through user experiences was inadequate; rates of change had become so rapid that products were obsolete before improvements could be added. Now, the strategy often used by successful design environments is to include human factors in design and development. When properly managed, products or systems that use human factors knowledge are more efficient, safer, and more pleasing to use because they are designed to accommodate human performance capabilities (Norman, 1988).

Human factors is an extremely broad technical and scientific discipline; founders of the first national and international human factors organisations came from such diverse fields as engineering, design, education, computer technology, psychology, and medicine. Through its diversity human factors is able to draw upon and combine knowledge from any area when working with human and system performance issues. Due to the complexity of human behaviour, human factors specialists emphasise in their work an iterative empirical approach. First, an initial recommendation or interface design is made and then laboratory or field studies are conducted to test this initial design (the prototype). Changes are made when deficits are identified; modifications are made; and further testing is then performed. This process continues until significant problems are no longer found. Finally, validation is achieved through observation in the field after system deployment.

This emphasis on empirical work tends to shape how human factors specialists perform their roles. Irrespective of the specific methodology chosen for gathering data about tasks, users, and the use of products, human factors work tends to result in product improvements likely to be economical, easy, and efficient to use from the beginning of use; the cost of and need to go back and fix problems when human factors is not used is avoided.

Human factors can also be called ergonomics. As the term “human factors” is in more common usage in the computer field, it is used for this article.

Human Factors and Computers

As with other technologies, WWII helped to stimulate the development of computers. The first models of computer used to manage information were primitive in comparison to the computers of today. They were designed by scientists and engineers to be used by scientists and engineers. These computer systems were difficult to operate and had to be closely watched during operation; users had to understand the technology for successful operation and tolerate problems, as technology-advanced computers became easier to operate. With today’s systems, the typical user does not need to understand technology; what is important is that a user understands how to tell a computer exactly what information is needed.

This progress in computer technology means that average users of computers and information technology (IT) are no longer just scientists or engineers; instead, they can be anyone who understands how to operate the computer information system they are using. While computer and IT systems are much easier to use, this does not
mean that there are not challenges faced. When working with information stored electronically or operating something with the help of a computer, problems can occur when a user misunderstands information presented to them, or they fail to correctly tell the computing system what is wanted. Literature on computers and electronic technology describes instances where there were serious negative consequences when information presented by a computer was misunderstood or systems were mistakenly told to do something different than what was wanted. The shooting down of Korean Airlines flight 007 in 1983 demonstrates some of the problems that can occur between the operator and a computer. Before take-off a crew member entered wrong data into an on-board computer. A warning was ignored as it appeared to be caused by another factor other than the entry of incorrect data. Subsequently the incorrect data caused the pilot to fly off course and into a sensitive area where the aircraft was shot down by a missile. Had the system been designed differently, so that the human activity context was better considered, then it would be likely that a tragic chain of events would not have been started.

To prevent such events from occurring, an emphasis on understanding how to design systems, where it is difficult for people to make mistakes or misunderstand, has emerged as a specialty within the field of human factors. The concept of human-computer interaction, or HCI, as a specialty within human factors emerged. In simple terms, HCI is the search for ways to make computers and complex information services accessible, usable, and acceptable to the non-specialist user.

At first, the emphasis of HCI was on physical aspects such as the size, location, and qualities of computer screens and controls. How people think when using computing and IT systems was added as it became more and more evident that how users think and understand is extremely critical in computer design. The subspecialties of cognitive engineering and usability followed—the former concerns understanding how people think when understanding systems, and the latter concerns how well people can understand and use systems.

Human factors and its related disciplines are now recognised as an important part of the computing system design process. Most computer and related system design approaches try to consider the needs and capabilities of users. With new products and technologies constantly entering the market, new problems are continually encountered—this underscores a continuing need to address human factors when designing computers and computing systems (Cooper, 1999).

The migration of paper-based forms to computer-based public information systems is the type of problem now faced. Work currently in progress in Sweden has found that the way a form looks on paper cannot be used on a computer screen. A computerised system had been developed that used exact copies of paper forms on computer screens. User error rates were extremely high, and the computer system was more costly to operate than its paper-based predecessor. The computer system had been designed without involvement of human factors specialists. Human factors specialists were asked to help correct system problems. The initial results of the human factors assessment reduced error rates and costs; work continues to bring performance to a desired level. The human factors specialists questioned and observed users. From those, it was possible to identify simple solutions to performance problems.

Public Information Systems, Computers, and Human Factors

Since public and private information systems use the same technology and function to exchange information between users and systems, is there any difference between the two? Should they be treated differently? Do the two have different needs?
Questions about difference and how human factors is connected are perhaps best answered by looking at the populations served and the reasons for the creation of any particular system. Private information systems generally serve segments of entire populations (exclusive) and make little or no attempt to accommodate those who lack needed skills. In contrast, public systems must at least have the goal of being usable by every member of a population (inclusive). The exclusive nature of private information systems means that during development and design there is a focus on meeting the needs of a target group that is part of an entire population. In contrast, public information systems generally must be developed and designed to at least have the goal of accessibility to an entire population. A second major difference between the two is that private information systems are oriented towards generating at least enough revenue to meet expenses, while public information systems are oriented towards providing service (which may or may not generate revenue).

While these differences may be subtle in some circumstances (e.g., a system used by a private, non-profit organisation or a system used by a fee-based public entity), it can be argued that, in some form, an inclusive or exclusive orientation is present.

How is this difference important with respect to human factors and public information systems? It is important because public information systems must be designed to be usable by the public—which includes everyone in a population. The goal of accessibility to an entire population means having to design for all levels of computer skills, education, and ability. A private information system is designed to be used by persons who are already familiar with computers and, if specialised knowledge/skills are needed, training is provided.

Any entity responsible for a public information system benefits from incorporating human factors knowledge and skills into any information system development or operation. The multiple levels of needs of users make understanding this diversity essential. Without human factors there is a much higher risk that the best design alternatives will not be found and selected—such as trying to move from paper forms to computer-based forms without considering the differences between entering data on paper and entering the same data onto a computer screen. As described in greater detail in the following section, human factors practices make certain that people can easily understand and use a system.

**HUMAN FACTORS AS A KEY ELEMENT IN PUBLIC SYSTEM DESIGN**

Including human factors in the earliest stages of any design process ensures that a product is defined in terms of user needs. Human factors input at these stages also helps project management to redirect resources to approaches that are most likely to have the greatest user benefit. Human factor specialist involvement throughout design processes results in catching problems early on; thus helping to reduce overall project costs. Finally, the ability to anticipate user responses continues to improve as successive prototypes more closely approximate the final product and actual field conditions. During design and development processes, human factors specialists base user interface and system design recommendations on an understanding of user needs, goals, characteristics, and expectations. Systems designers then work with human factors specialists to translate these stated needs into specific technical design requirements that may be implemented within cost targets. As noted earlier, the human factors specialist can work with public information system development and design processes to balance usability requirements with user constraints, system requirements, and development costs. The result can be that the final product functions as desired and in ways that are easily usable (Bailey, 1996).
PLANNING FOR HUMAN FACTORS DURING PUBLIC INFORMATION SYSTEM DEVELOPMENT

Information systems’ planning is a common problem for organisations, and planning for human factors is a particular problem within the overall problem of design (Kuark, 1996). The traditional approach to planning IT systems is called the systems development life cycle (SDLC) method (Davis & Olson, 1985). This approach can be summarised as a linear checklist of activities undertaken in a series of phases that begins with planning and ends with system termination. To put it another way, SDLC is a planning process that separates an IT system problem into its constituent parts, treats each step separately, and then unifies the parts into a whole at the end (Lange-fors, 1973). This approach has been criticised as too concentrated on technology at the expense of users and product performance (e.g., Noyes et al., 1996). To keep the valuable parts of the SDLC method there is a movement to integrate human factors into SDLC (Zhang, Carey, Te’eni, & Tremaine, 2005). Whether integrated in with SDLC or another methodology, HCI development and design is the process of creating quickly all or part of a system in the form of a simulation or prototype (e.g., on paper or a nonworking sample displayed on a computer screen). The advantage of this method is that it allows user feedback early enough to accommodate major structural changes before extensive development investments are committed. This use of prototyping is a team process which helps to overcome the limitations of SDLC. The early SDLC model has been described as too linear, lacking a group planning orientation and an actual reflection of real world conditions (e.g., Wanninger & Dickson, 1992). Now the emphasis is on using the systematic features of SDLC from a human factors perspective; technical decisions are based on an understanding of human needs and capabilities (e.g., Zhang et al., 2005). The following section on user-centred design describes the most commonly used model promoted by human factors professionals and user-oriented designers.

USER-CENTRED DESIGN

User-centred design (UCD) refers to the design of interaction between users and the system, called interaction design (Preece, Rogers, & Sharp, 2002). It models a system from a user perspective and focuses on the usability of an interactive software system. The core objective is to effectively support users in executing their tasks (Earthly, 2001).

Usability is recognised as one of the most important quality characteristics of software intensive systems and products. Usability gives many benefits including “increased productivity, enhanced quality of work, improved user satisfaction, reductions in support and training costs and improved user satisfaction” (ISO13407, 1999).

The prevailing paradigm of developing usable products and systems (or UCD) is that usable products are created through processes of user-centred design. The UCD process model is illustrated in Figure 1. Achieving quality in use requires this type of user-centred design process and the use of appropriate usability evaluation techniques. Usability is defined as a high level quality objective: to achieve effectiveness, efficiency, and satisfaction. This requires not only ease of use but also appropriate functionality, reliability, computer performance, satisfaction, comfort, and so on.

UCD and Usability

The role of UCD in a development effort is to deal with user needs in a way that highlights potential problems and ensures that products, systems, and services will succeed because they are based on appropriate UCD and usability. The applied discipline of cognitive engineering leans heavily on
the knowledge and methods developed by human experimental psychology and, to a lesser extent, on applied physiology and related human sciences to carry this goal out.

Usability Facilities

Usability laboratories have become an important tool. These laboratories, together with appropriate field-kit evaluations, enable us to meet the growing number of requests for usability support, chiefly user-based evaluations of development prototypes and competitors’ products. Together with the appropriate development processes, laboratory studies help predict and deal with specific usability problems during product development. Such a laboratory also provides an extremely powerful tool to identify and publicise general usability issues that affect overall product use. Rubin (1994) describes usability testing in detail and gives examples of typical usability laboratories.

IMPLEMENTATION ISSUES

Although improved technology will always have a critical role in system design, it is often the case that human factors considerations will take up the majority of the time of IT designers and managers. Much is known about the nature of human error, the conditions that encourage error, and hardware/software designs that are error resistant (Norman, 1990), and much of this is now well recognised in IT training literature (Salvendy, 1997). While human factors is recognised and used by many information system developers and designers, there are those who take the perspective that users who want access must accommodate themselves to an information system.

The attitude of the employees’ response for administering a public information system is also critical for success. New users or those with problems may need to ask an employee (a human-human interface) for help. Employees who have a negative attitude will too often give the user a negative attitude towards the system (Cialdini, 1993). Including employees in processes will help to avoid the problem of employees undermining the operation of a public information system; following are some points to use in the avoidance of employee resistance.

Cognitive Aspects of Implementation

Overcoming employee resistance is a problem in cognitive change. Human factors texts and refer-
ence books describe how computerisation alters the flow and content of information, changes job content, or affects relationships between organisational members (e.g., Bailey, 1996; Dix, Finlay, Abowd, & Beale, 1998; Helander, 1997). A key finding was that the primary issue was not computing itself, but rather perceptions of the method of implementing it. It is precisely in this area that human factors become important by including assessment of organisations during public information system changes.

**Cognitive Perception**

In IT projects there are four common cognitive perceptions that must be overcome by employees: (1) automation is mandated arbitrarily; (2) the new computer system will be unreliable; (3) the new system will increase rather than decrease the work burden; and (4) they (employees) will neither understand a system nor be able to operate it. Free and open communications throughout an IT implementation process is an important avenue for reducing employee resistance coming from these issues. Negative perceptions regarding the introduction of IT may be overcome to a significant extent through the encouragement of employee decision making during an IT introduction process.

**Attitudes**

Although user attitudes tend to be against change, once new technology is seen as bringing desired benefits, attitudes will begin to adapt. In particular, acceptance is much more likely when computing is presented as complementary to human skills, enhancing rather than replacing them (Petheram, 1989; Rosenbrock, 1981). Changing employee attitudes is all the more important since word of mouth is a critical aspect of the process by which technological innovations are spread (Czepiel, 1974). Dickson, a pioneer in the study of human relations and IT noted that, when it comes to management information systems, it is essential to involve people as a component, knowledge of their behaviour as a part of the system is important to the success of the entire field (Dickson, 1968).

The human factor in IT involves both teamwork and leadership. If a leader attempts to bring about IT change in an authoritarian manner, the result may be resistance, lack of effectiveness, and even outright failure. On the other hand, if a leader is able to mobilise the cognitive pressure of professionalism in favour of IT change, then an organisational culture of acceptance is possible (Prasad & Prasad, 1994).

**FUTURE TRENDS**

When considering the future of human factors in public information systems, it is useful to first recognise that an astonishingly rapid rate of technological change has been and is the norm for computing systems. Whole buildings and highly trained teams were once needed for a single computer; in contrast, more powerful systems can now be found on the top of the desk of the least-skilled person in an organisation. Given this rapid and dramatic pace of change and development, it is challenging to predict future directions.

Despite this dramatic pace which defies the imagination it is possible to observe that whatever technology may bring the core emphasis of human factors will remain unchanged. For any technological change to be effective, it must be readily understandable and usable by an average user. For example, while nearly instantaneous processing and presentation of data is becoming the norm, that data are of no value if confusing or overwhelming.

Any future system, regardless of any technological advance it may achieve, must include in its design consideration how humans comprehend, manage, and process information. For example, Miller (1956) reported that the average person is unable to remember more than seven pieces
of information at one time. A computing system that requires that a user remember eight pieces of information to successfully complete an operation will therefore have high rates of user error. It is this kind of simple, yet critical, understanding of human capability that must always be included in design.

Thus, technologies and designs of the future will always need to include recognition of human limitations in any interface design. Toolkits that contain information about human capabilities will make it possible for researchers and designers to consistently include consideration of the human user in any final product.

CONCLUSION

New technologies are often seen as an ultimate solution. While this is essentially correct, it is also necessary to recognise that improved technology does not change human capability. Computers and computing systems, as with public information systems, can only be as effective as users are capable. Designs that expect users to learn to perform beyond usual capabilities ignore the reality that humans are limited and unlike technology, cannot be improved or upgraded. For this reason it is essential that the concept of user-centred design be part of any public information system design process.

As implied, the introduction into IT system development of user-centred design procedures ensures that success stories associated with usability engineering will continue. Advanced development projects that examine psychological factors underlying consumer reactions and expectations include user-centred evaluations of prototypes and match human capabilities with system designs. These are most likely to result in public information systems that are accepted by both the public and governmental employees.

The inclusion of human factors into public information system development and design processes will, over the life of a system, reduce costs through the avoidance of the need to correct problems caused by errors or through difficulty in using the system. To successfully achieve this integration strong leadership that requires human factors elements in a system is necessary. Strategies such as specifying ISO 13407 (1999) as the standard during development and design are recommended as a way to be sure that human factors will be included.

Human Factors in Public Information Systems

**KEY TERMS**

**Cognitive Engineering:** Understanding and predicting how changes in a task environment will influence task performance.

**Human-Computer Interaction (HCI):** The study of people, computer technology, and the ways these influence each other (Dix et al., 1998).

**Human Factors (or Ergonomics):** The scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data, and methods to design in order to optimise human well-being and overall system performance (IEA, 2005).
**Interface:** A point in any human-computer system where information is exchanged. Interface designs that do not take into consideration human capabilities will likely have higher than desirable rates of human error.

**Usability:** The effectiveness, efficiency, and satisfaction with which specified users can achieve specified goals in particular environments.

**User-Centred Design:** During the design of systems or products the capabilities of end users (humans) are considered so that the final system or product is readily usable and designed so that the likelihood of error is minimised.

**User Interface:** The way that a human and computer system exchange information. Both hardware and software are part of the user interface. The screen, keyboard, and mouse are the most common hardware combination; any other hardware design that can be used to exchange information is also a user interface. The software arranges the information (e.g., sequence, quantity, manner requested, etc.). Human factors focuses on making certain that information is presented in a way that facilitates understanding.

Chapter 1.6
Task Analysis at the Heart of Human–Computer Interaction

Dan Diaper
Middlesex University, UK

INTRODUCTION

The history of task analysis is nearly a century old, with its roots in the work of Gilbreth (1911) and Taylor (1912). Taylor’s scientific management provided the theoretical basis for production-line manufacturing. The ancient manufacturing approach using craft skill involved an individual, or a small group, undertaking, from start to finish, many different operations so as to produce a single or small number of manufactured objects. Indeed, the craftsperson often made his or her own tools with which to make end products. Of course, with the growth of civilisation came specialisation, so that the carpenter did not fell the trees or the potter actually dig the clay, but still each craft involved many different operations by each person. Scientific management’s novelty was the degree of specialisation it engendered: each person doing the same small number of things repeatedly.

Taylorism thus involved some large operation, subsequently called a task, that could be broken down into smaller operations, called subtasks. Task analysis came into being as the method that, according to Anderson, Carroll, Grudin, McGrew, and Scapin (1990), “refers to schemes for hierarchical decomposition of what people do.” The definition of a task remains a “classic and under-addressed problem” (Diaper, 1989b). Tasks have been differently defined with respect to their scope: from the very large and complex, such as document production (Wilson, Barnard, & MacLean, 1986), to the very small, for example, tasks that “may involve only one or two activities which take less than a second to complete, for example, moving a cursor” (Johnson & Johnson, 1987). Rather than trying to define what is a task by size, Diaper’s (1989b) alternative is borrowed from conversation analysis (Levinson, 1983). Diaper suggests that tasks always have well-defined starts and finishes, and clearly related activities in between. The advantage of such a definition is that it allows tasks to be interrupted or to be carried out in parallel.

Task analysis was always involved with the concept of work, and successful work is usually defined as achieving some goal. While initially applied to observable, physical work, as the field of ergonomics developed from World War II, the
task concept was applied more widely to cover all types of work that “refocused attention on the information processing aspect of tasks and the role of the human operator as a controller, planner, diagnostician and problem solver in complex systems” (Annett & Stanton, 1998). With some notable exceptions discussed below, tasks are still generally defined with people as the agents that perform work. For example, Annett and Stanton defined task analysis as “[m]ethods of collecting, classifying and interpreting data on human performance.”

BACKGROUND

Stanton (2004) suggests that “[s]implistically, most task analysis involves (1) identifying tasks, (2) collecting task data, (3) analyzing this data so that the tasks are understood, and then (4) producing a documented representation of the analyzed tasks (5) suitable for some engineering purpose.” While there are many similar such simplistic descriptions, Stanton’s five-item list provides an adequate description of the stages involved in task analysis, although the third and fourth are, in practice, usually combined. The following four subsections deal with them in more detail, but with two provisos. First, one should always start with Stanton’s final item of establishing the purpose of undertaking a task analysis. Second, an iterative approach is always desirable because how tasks are performed is complicated.

The Purpose of a Task Analysis

Task analysis has many applications that have nothing to do with computer systems. Even when used in HCI (human-computer interaction), however, task analysis can contribute to all the stages of the software-development life cycle. In addition, task analysis can make major contributions to other elements associated with software development, in particular the preparation of user-support systems such as manuals and help systems, and for training, which was the original application of hierarchical task analysis (HTA; Annett & Duncan, 1967; Annett, Duncan, Stammers, & Gray, 1971). HTA was the first method that attempted to model some of the psychology of people performing tasks.

Although infrequently documented, identifying the purposes for using task analysis in a software project must be the first step (Diaper, 1989a) because this will determine the task selection, the method to be used, the nature of the outputs, and the level of analysis detail necessary. The latter is vital because too much detailed data that does not subsequently contribute to a project will have been expensive to collect, and too high a level will require further iterations to allow more detailed analysis (Diaper, 1989b, 2004). Decomposition-orientated methods such as HTA partially overcome the level-of-detail problem, but at the expense of collecting more task data during analysis. Collecting task data is often an expensive business, and access to the relevant people is not always easy (Coronado & Casey, 2004; Degen & Pedell, 2004; Greenberg, 2004). Within a software-development life cycle, Diaper (2004) has suggested that one identify all the stages to which a task analysis will contribute and then make selections on the basis of where its contribution will be greatest.

Identifying Tasks

In the context of task scenarios, which Diaper (2002a, 2002b) describes as “low fidelity task simulations,” Carroll (2000) rightly points out that “there is an infinity of possible usage scenarios.” Thus, only a sample of tasks can be analysed. The tasks chosen will depend on the task analysis’ purpose. For new systems, one usually starts with typical tasks. For existing systems and well-developed prototypes, one is more likely to be concerned with complex and difficult tasks, and important and critical ones, and, when a system
is in use, tasks during which failures or problems have occurred. Wong (2004) describes his critical decision method as one way of dealing with the latter types of tasks.

Unless there are overriding constraints within a software project, then task analysts should expect, and accept, the need to be iterative and repeatedly select more tasks for analysis. Since the coverage of all possible tasks can rarely be complete, there is a need for a systematic task selection approach. There are two issues of coverage: first, the range of tasks selected, and second, the range of different ways that tasks may be carried out, both successfully and unsuccessfully.

One criticism of task analysis is that it requires extant tasks. On the other hand, all tasks subjected to task analysis are only simulations as, even when observed in situ, a Hiesenberg effect (Diaper, 1989b) can occur whereby the act of observation changes the task. Often, it is desirable to simulate tasks so that unusual, exceptional, and/or important task instances can be studied and, of course, when a new system or prototype is not available.

**Collecting Task Data**

There are many myths about task analysis (Diaper et al., 2003), and one of the most persistent involves the detailed observation of people performing tasks. Sometimes, task-analysis data do involve such observation, but they need not, and often it is inappropriate even with an existing system and experienced users.

Johnson, Diaper, and Long (1984; see also Diaper, 1989b, 2001) claim that one of the major strengths traditionally associated with task analysis is its capability to integrate different data types collected using different methods. The critical concept is that of fidelity. According to Diaper (2002a, 2002b), “fidelity, a close synonym is validity, is the degree of mapping that exists between the real world and the world modelled by the (task) simulation,” although as he says parenthetically, “N.B. slightly more accurately perhaps, from a solipsistic position, it is the mapping between one model of the assumed real world and another.”

At one end of the task-fidelity spectrum there is careful, detailed task observation, and at the other, when using scenarios of novel future systems, task data may exist only in task analysts’ imagination. Between, there is virtually every possible way of collecting data: by interviews, questionnaires, classification methods such as card sorting, ethnography, participative design, and so forth. Cordingley (1989) provides a reasonable summary of many such methods. The primary constraint on such methods is one of perspective, maintaining a focus on task performance. For example, Diaper (1990) describes the use of task-focused interviews as an appropriate source of data for a requirements analysis of a new generation of specialised computer systems that were some years away from development.

**Task Analysis and Task Representation**

The main representation used by virtually all task analysis methods is the activity list, although it goes by many other names such as a task protocol or interaction script. An activity list is a prose description of one or more tasks presented as a list that usually has a single action performed by an agent on each line. Each action on an activity-list line may involve one or more objects, either as the target of the action or as support for the action, that is, as a tool. An important component of an activity list should be the identification of triggers (Dix, Ramduny-Ellis, & Wilkinson, 2004). While most tasks do possess some sequences of activity list lines in which the successful completion of an action performed on one line triggers the next, there are many cases when some event, either physical or psychological, causes one of two or more possible alternatives to occur.
Diaper (2004) suggests that an activity list is sometimes sufficient to meet a task analysis’ purposes. He suggests that one of the main reasons for the plethora of task analysis methods is the volume of data represented in the activity list format, often tens, if not hundreds, of pages. As Benyon and Macaulay (2002) discuss, the role of task analysis methods applied to activity lists is not only to reduce the sheer amount of the data, but to allow the data to be abstracted to create a conceptual model for designers.

The two oldest and most widely cited task-analysis methods are HTA (Annett, 2003, 2004; Shepherd, 2001), and goals, operators, methods, and selection rules (GOMS; Card, Moran, & Newell, 1983; John & Kieras, 1996; Kieras, 2004). HTA is often misunderstood in that it produces, by top-down decomposition, a hierarchy of goals, and these are often confused with physical or other cognitive activities. HTA uses rules to allow the goal hierarchy to be traversed. Analyses such as HTA provide a basic analysis (Kieras) that can then be used by methods such as GOMS. While often perceived as too complicated, it is claimed that GOMS provides good predictive adequacy of both task times and errors.

There are between 20 and 200 task analysis methods depending on how one counts them. This presents a problem as different methods have different properties and are suitable for different purposes. An agreed taxonomy of methods for method selection is still unavailable. In Diaper and Stanton (2004a), there are half a dozen different taxonomies. Diaper (2004), rather depressingly, suggests, “in practice, people either choose a task analysis method with which they are familiar or they use something that looks like HTA.”

Limbourg and Vanderdonkt (2004) produced a taxonomy of nine task analysis methods, abridged in Table 1. The methods have been reorganized so that they increase in both complexity and expressiveness down the table. References and further descriptions can be found in Diaper and Stanton (2004a).

As can be seen from Table 1, there is no accepted terminology across task analysis methods. An exception, noted by Diaper and Stanton (2004b), is that of goals and their decomposition and generalisation.

A number of recent attempts have been made to classify tasks into a small number of subtasks (Carroll, 2000; Sutcliffe, 2003; Ormerod & Shepherd, 2004). The latter’s subgoal template (SGT) method, for example, classifies all information handling tasks into just four types: act, exchange, navigate, and monitor. Underneath this level, they have then identified 11 task elements. The general idea is to simplify analysis by allowing the easy identification of subtasks, which can sometimes be reused from previous analyses.

**TASK ANALYSIS AT THE HEART OF HUMAN-COMPUTER INTERACTION**

Diaper and Stanton (2004b) claim that “[t]oday, task analysis is a mess.” Introducing Diaper (2002c), Kilgour suggests that Diaper should consider the “rise, fall and renaissance of task analysis.” While Diaper argues that really there has been no such fall, Kilgour is right that there was a cultural shift within HCI in the 1990s away from explicitly referring to task analysis. Diaper’s oft-repeated argument has been that whatever it is called, analysing tasks has remained essential and at the heart of virtually all HCI work. Diaper (2002a, 2002b) comments, “It may well be that Carroll is correct if he believes that many in the software industry are disenchanted with task analysis…It may well be that the semantic legacy of the term “task analysis” is such that alternatives are now preferable.”
Task Analysis at the Heart of Human-Computer Interaction

Central to Diaper’s current definition of task analysis, and the primary reason why task analysis is at the heart of virtually all HCI work, is the concept of performance. His definition (Diaper, 2004; Diaper et al., 2003) is as follows:

Work is achieved by the work system making changes to the application domain. The application domain is that part of the assumed real world that is relevant to the functioning of the work system. A work system in HCI consists of one or more human and computer components and usually many other sorts of thing as well. Tasks are the means by which the work system changes the application domain. Goals are desired future states of the application domain that the work system should achieve by the tasks it carries out. The work system’s performance is deemed satisfactory as long as it continues to achieve its goals in the application domain. Task analysis is the study of how work is achieved by tasks.

Most models and representations used in software engineering and HCI are declarative; that is, they describe things and some of the relationships between things, but not the processes that transform things over time. For example, data-flow diagrams are atemporal and acausal and specify only that data may flow, but not when and under what circumstances. In contrast, it is essential, for all successful task-analytic approaches, that performance is modeled because tasks are about achieving work.

Based on Dowell and Long’s (1989) and Long’s (1997) general HCI design problem, Diaper’s (2004) systemic task analysis (STA) ap-

proach emphasizes the performance of systems. While STA is offered as a method, it is more of an approach in that it deals with the basics of undertaking the early stages of a task analysis and then allows other analysis methods and their representations to be generated from its activity list output. The advantage of STA over most other task analysis methods is that it models systems and, particularly, the performance of the work system. STA allows the boundary definition of a work system to change during a task so that different constituent subtasks involve differently defined work systems, and these may also be differently defined for the same events, thus allowing alternative perspectives.

The novelty of STA’s view of work systems is threefold. First, as the agent of change that performs work, a work system in HCI applications is not usually anthropocentric, but a collection of things, only some of them human, that operate together to change the application domain. Second, it is the work system that possesses goals concerning the desired changes to the application domain rather than the goals being exclusively possessed by people. Third, STA is not monoteleological, insisting that work is never achieved to satisfy a single goal, but rather it states that there are always multiple goals that combine, trade off, and interact in subtle, complex ways.

STA’s modeling of complex work systems has recently been supported by Hollnagel (2003b) in cognitive task design (CTD); he claims that “cognition is not defined as a psychological process unique to humans, but as a characteristic of systems performance, namely the ability to maintain control. The focus of CTD is therefore the joint cognitive system, rather than the individual user.” Hollnagel’s formulation of CTD is more conservative than STA’s; for example, CTD is sometimes monoteleological when he refers to a single goal, and he restricts nonhuman goals to a limited number of things, albeit “a growing number of technological artefacts” capable of cognitive tasks. In STA, it is not some limited number of technological artefacts that possess goals and other cognitive properties, but the work system, which usually has both human and nonhuman components.

**FUTURE TRENDS**

While recognising the difficulty, perhaps impossibility, of reliably predicting the future, Diaper and Stanton (2004b) suggest that one can reasonably predict possible futures, plural. They propose that “[f]our clusters of simulated future scenarios for task analysis organized post hoc by whether an agreed theory, vocabulary, etc., for task analysis emerges and whether task analysis methods become more integrated in the future.” While not predicting which future or combination will occur, or when, they are however confident that “[p]eople will always be interested in task analysis, for task analysis is about the *performance* of work,” even though they admit that “[l]ess certain is whether it will be called task analysis in the future.”

Probably because of its long history, there is an undoubted need for the theoretical basics that underpin the task concept and task analysis to be revisited, as Diaper (2004) attempts to do for the development of STA. Diaper and Stanton (2004b) also suggest that some metamethod of task analysis needs to be developed and that more attention needs to be placed on a wide range of types of validation, theory, methods, and content, and also on methods’ predictive capability to support design and for other engineering purposes (Annett, 2002; Stanton, 2002; Stanton & Young, 1999). At least two other areas need to be addressed in the future: first, how work is defined, and second, the currently ubiquitous concept of goals.

Task analysis has always been concerned with the achievement of work. The work concept, however, has previously been primarily concerned with employment of some sort. What is needed, as Karat, Karat, and Vergo (2004) argue, is a broader definition of work. Their proposals are consistent...
with STA’s definition of work being about the work system changing the application domain. They persuasively argue for nonemployment application domains, for example, domestic ones. Thus, a home entertainment system, television, or video game, for example, could be components of a work system, and the goals to be achieved would be to induce pleasure, fun, or similar feelings in their users. That such application domains are psychological and internal to such work systems’ users, rather than the more traditional changes to things separate and external to some work system’s components, is also consistent with STA’s conceptualisation of task analysis.

Finally, Diaper and Stanton (2004b) broach, indeed they attempt to capsize, the concept of goals. They question whether the goals concept is necessary, either as what causes behavior or as an explanation for behavior, which they suggest, based on several decades of social psychological research, is actually usually post hoc; that is, people explain why they have behaved in some manner after the event with reference to one or more goals that they erroneously claim to have possessed prior to the behavior. Not only in all task analysis work, but in virtually every area of human endeavour, the concept of goals is used. Abandoning the concept as unnecessary and unhelpful is one that will continue to meet with fierce resistance since it seems to be a cornerstone of people’s understanding of their own psychology and, hence, their understanding of the world. On the other hand, academic researchers have a moral duty to question what may be widely held shibboleths. Currently, goal abandonment is undoubtedly a bridge too far for nearly everyone, which is why STA still uses the goals concept, but greater success, if not happiness, may result in some distant future if the concept is abandoned. At the least, it is time to question the truth and usefulness of the goals concept.

CONCLUSION

Two handbooks (although at about 700 pages each, neither is particularly handy) on task analysis have recently become available: Diaper and Stanton (2004a) and Hollnagel (2003a). Both are highly recommended and, while naturally the author prefers the former because of his personal involvement, he also prefers the Diaper and Stanton tome because it provides more introductory material, is better indexed and the chapters more thoroughly cross-referenced, comes with a CD-ROM of the entire book, and, in paperback, is substantially cheaper than Hollnagel’s book. No apology is made for citing the Diaper and Stanton book frequently in this article, or for the number of references below, although they are a fraction of the vast literature explicitly about task analysis. Moreover, as task analysis is at the heart of virtually all HCI because it is fundamentally about the performance of systems, then whether called task analysis or not, nearly all the published HCI literature is concerned in some way with the concept of tasks and their analysis.

Task Analysis at the Heart of Human-Computer Interaction

**KEY TERMS**

**Activity List:** A prose description of a task or subtask divided into lines to represent separate task behaviors and that usually has only one main agent and one action per line.

**Application Domain:** That part of the assumed real world that is changed by a work system to achieve the work system’s goals.

**Goal:** A specification of the desired changes a work system attempts to achieve in an application domain.

**Performance:** The quality, with respect to both errors and time, of work.

**Subtask:** A discrete part of a task.

**Task:** The mechanism by which an application domain is changed by a work system to achieve the work system’s goals.

**Work:** The change to an application domain by a work system to achieve the work system’s goals.

**Work System:** That part of the assumed real world that attempts to change an application domain to achieve the work system’s goals.

ABSTRACT

In this chapter the evaluation of human computer interaction (HCI) with mobile technologies is considered. The ISO 9241 notion of ‘context of use’ helps to define evaluation in terms of the ‘fitness-for-purpose’ of a given device to perform given tasks by given users in given environments. It is suggested that conventional notions of usability can be useful for considering some aspects of the design of displays and interaction devices, but that additional approaches are needed to fully understand the use of mobile technologies. These additional approaches involve dual-task studies in which the device is used whilst performing some other activity, and subjective evaluation on the impact of the technology on the person.

INTRODUCTION

This chapter assumes that ‘usability’ is not a feature of a product, that is, it does not make sense to call a product itself ‘usable’. Rather, usability is the consequence of a given user employing a given product to perform a given activity in a given environment. Holcomb and Tharp (1991) proposed a ‘model’ of interface usability, which is illustrated by Table 1. The definitions presented in Table 1 arose from consideration of the user interface of desk-based computers. However, it ought to be apparent that the majority of the components are defined in terms of an individual’s perceptions of features of the user interface.

The International Standards Organization has a number of standards relevant to human-computer interaction (Bevan, 2001). Current standards for mobile devices tend to focus on product attributes, for example, ISO 18021: Information Technology —User Interface for Mobiles (2001) provides interface specifications for Personal Digital Assistants. Other Standards have recognized the multifaceted nature of usability and have sought to encourage an approach that is similar to Quality Assessment (Earthey et al., 2001). Demonstrating compliance with the standards requires analysts to document their evaluation, demonstrating how it meets the objectives of the standard. The
Evaluating Mobile Human-Computer Interaction

The definition of usability offered by the International Standards Organization, that is, in ISO9241, part 11, is, “... the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use.” (ISO9241-11, 1998).

The implications are that, first, usability is the consequence of a given user employing a given product to perform a given activity in a given environment (as stated) and, second, that it is possible to measure aspects of this relationship in terms of effectiveness, efficiency, and user satisfaction. It is important to note that these three aspects are inter-connected and that any evaluation activity ought to try to measure some aspect of each (Frøkjær et al., 2000).

**Defining Evaluation Targets**

If one is able to speak of measures, then it makes sense to be able to determine some criteria that indicate good or poor performance on these measures. Good et al. (1986) proposed that it is important to define both evaluation targets and metrics that relate to these targets. For example, in a study of conferencing systems, Whiteside et al. (1988) identified 10 attributes that they felt reflected the use of the conferencing system, for example, ranging from a fear of feeling foolish to a number of errors made during task performance. For each attribute, Whiteside et al. (1988) defined a method for collecting data about that attribute, for example, questionnaires, observation, and so forth, and then set performance limits relating to best, worst, and planned levels. A study of a wearable computer for paramedics (Baber et al., 1999) used this concept to produce Table 2.

In Table 2, three measures of performance were undertaken, that is, predictive modeling (using critical path analysis), user trials, and performance improvement arising from practice. In addition, three subjective evaluation methods were used. Table 2 shows how the system met (or exceeded) some of the target criteria but fell below the target

for time (although it is not within the ‘worst’ case range). One benefit of such a technique is to allow the design team to decide whether there is a need for more effort to refine the device, or whether, having met (some or all of) the requirements, the design process can be closed.

The ISO9241 notion of usability requires the concept of evaluation targets, for example, one could begin with a target of “66% of the specified users would be able to use the 10 main functions of product X after a 30 minute introduction.” Once this target has been met, the design team might want to increase one of the variables, for example, 85% of the specified users, or 20 main functions, or 15 minute introduction, or might want to sign-off that target.

Why Conduct Evaluation?

The concept of usability that is used in this chapter (and in ISO9241) implies that changing any one of the variables {user, activity, device, environment} can have an impact on usability. This implication points to the well-known assertion that an activity that a designer of the product might find easy to perform could prove problematic for a user who has had little or no previous experience of the product. It also points to potential issues relating to the usability of mobile technology, particularly through consideration of the environment. If we think about sending a text-message from a handheld device, such as a mobile telephone or a Blackberry™, the activities involved could be somewhat different while sitting on a train versus walking down a busy street. This change in environmental setting will have a marked effect on usability of the device. This does not necessarily result from the design of the device itself but rather from the interactions between design, use, and environment. As Johnson (1998) pointed out, “HCI methods, models and techniques will need to be reconsidered if they are to address the concerns of interaction on the move.” (Johnson, 1998). The question for this chapter, therefore, is how best to address the relationship between user, activity, product, and environment in order to evaluate the usability of mobile technology. Related to this question is how evaluation might capture and measure this relationship, and then what can designers do to improve usability. This latter point is particularly problematic if one assumes that design is about creating a product rather than about creating an interaction.

Before considering these questions, it is worth rehearsing why one might wish to conduct evaluation. Baber (2005) notes that the primary reason for conducting evaluation, in HCI, is to influence design (ideally, to improve the product). This implies that evaluation ought never to be a one-off activity to be conducted at the end of the design lifecycle in order to allow a design to be signed-off (Gould & Lewis, 1985; Johnson, 1992). Rather, it means the following:

1. Evaluation is a recursive activity that cuts across the entire design lifecycle, for exam-
Evaluating Mobile Human-Computer Interaction

...ple, software engineers will run versions of the code to debug and check; product designers will continually critique and refine their concepts. What is not always apparent is the manner in which these processes could (or indeed ought) be made formal and to result in something that can be communicated to other members of the design team.

2. Evaluation should be incorporated into as many stages of design as possible—this points to (i) but also raises that questions of recording and communicating the results of evaluation in a manner that can be beneficial to the design process.

3. Evaluation should be designed to maximize the impact of the evaluation of the design stage in which it is used—the suggestion is that, rather engaging in evaluation as a mandated exercise to allow sign-off between stages, it ought to be an activity that positively advances the design process.

4. Evaluation should guide and inform design activity—the results of any evaluation should be reported in a manner that can lead to change in the design and can be reported in a manner that is transparent and reliable.

A final point to note is that evaluation is a process of comparing the product against something else, for example, other products, design targets, requirements, standards. Thus, evaluation requires a referent model (Baber, 2005). It is naïve to believe that one can “evaluate” something in a vacuum, that is, to think that one can take a single product and “evaluate” it only in terms of itself. In many ways this is akin the concept of a control condition in experimental design; one might be able to measure performance, but without knowing what would constitute a baseline for the measure, it is not possible to determine whether it is good or bad.

Defining Referent Models

While it might be fairly clear as to why comparison requires a referent model, there is a problem for novel technologies. After all, the point of these technologies is to move beyond the conventional desk-bound personal computers and this will ultimately create new forms of interaction. However, the move to different technologies makes it hard to establish a sensible basis for evaluation. What is the referent model for mobile HCI?

A common form of mobile technology is the digital tour-guide that, knowing where the user is (using Global Positioning Satellite (GPS) to determine location) and what the user is doing, can provide up-to-the-minute information to help the user. There are few, if any, products that are like these concepts, so what constitutes a referent? At one level, this is simply because future HCI is attempting to develop approaches to interaction with technology for which there are no existing models. The answer to this question, the author suggests, comes from the assertion at the start of this chapter: usability is not a characteristic of the product, but the result of the interactions between user, product, activity, and environment. If we assume that tourists have a variety of strategies and artifacts that they currently use to find out where they are or to find out interesting information about a particular location, for example, maps, books, leaflets, other people. One could ground an initial evaluation of using the product to perform a given set of activities in comparison with existing practices. Conducting evaluation against other products in terms of a set of activities offers the analyst the following benefits:

1. The evaluation will cover a range of functions on the products. It is important to ensure that the comparison provides a fair and accurate view of the product. After all, it is not really the point of evaluation to just demonstrate the product X is better than product Y—partly because there are bound
to be occasions when products X and Y are similar, or where product Y is better than product X, and partly because simply knowing that X > Y tells us very little about how to improve X (or Y) or why X is superior.

2. The focus of the evaluation is less on product functioning than on user activity. This might appear, at first glance, to be tautological—surely product evaluation is about evaluating the product? This is, of course, true in a technical sense. However, HCI is about human-computer interaction, and the defining feature of this relationship is the interaction (rather than either human or computer). If one is concerned with technical evaluation then, perhaps some of the features to be included in a comparison table (like the one shown in Table 2) would be some of the technical features, for example, processor speed, RAM, memory, and so forth.

3. As the evaluation is concerned with user activity (as opposed to product functioning), the type of metrics that could be applied may well change. When comparing user activity on two or more products, it is important to decide what information is really being sought. Do we want to know only that X > Y? Or do we want to know that using product X or Y have differing effects on user activity?

In the field of mobile and wearable computers, much of the evaluation research has focused on comparing performance on a wearable computer with performance using other media. Thus, studies might compare performance using a wearable computer, say to perform a task that involves following instructions, and find that sometimes performance is superior in the paper condition (Siegel & Bauer, 1997; Baber et al., 1999) and sometimes it is superior in the wearable computer condition (Bass et al., 1995, 1997; Baber et al., 1998). This highlights the potential problem of comparing disparate technologies in an evaluation; it is not clear that any differences in performance are due to the experiment favoring one technology over another or whether there are other factors at play here. For example, a common observation is that people using the wearable computer tend to follow the instructions laid out on the display, whereas people using paper tend to adopt a more flexible approach (Siegel & Bauer, 1997; Baber et al., 1999). The notion that technology influences the ways in which people work is often taken as ‘commonsense’ by Human Factors engineers. However, the question of how and why such changes arise ought to have a far deeper impact on evaluation than is currently the case. As mentioned earlier, one way to deal with this problem is to focus on activities that people are performing using a variety of products. However, this will only cope with part of the problem. For instance, the electronic tour-guide given could be evaluated in comparison with other ways of performing activities, but this does not tell us whether any differences between the electronic tour-guide and the other products are due to the concept or to the realization of the concept or to changes in the activity arising from the use of the device. In other words, if we find that the electronic tour-guide performs less well than speaking to someone, is this because the tour-guide lacks information, or because it lacks clear presentation of information, or because it lacks speedy access to the information, or because it lacks flexibility of response, or because of some other reason (the evaluation could point to all of these, not to specific reasons).

At one level, the evaluation of mobile HCI calls for the application of current evaluation techniques. However, there are other aspects of future HCI that call for rethinking of evaluation. In other words, it might not be entirely appropriate to take methods that have proven useful for evaluating desktop HCI and apply these to future HCI. As Wilson and Nicholls (2002) point out in discussing the evaluation of virtual environments:
Evaluating Mobile Human-Computer Interaction

There are only a limited number of ways in which we can assess people’s performance. We can measure the outcome of what they have done, we can observe them doing it, we can measure the effects on them of doing it or we can ask them about either the behavior or its consequences. (Wilson & Nicholls, 2002)

The underlying assumption here is that human behavior is measurable in a finite number of ways. Combining this assertion with the need to study the relationship between user, activity, device, and environment, it becomes apparent that evaluation of user interaction with mobile activity can be reduced to a small number of requirements. Furthermore, the ISO 9241 notions of efficiency, effectiveness, and satisfaction point to the approaches outlined by Wilson and Nicholls (2002). For example, efficiency could be considered in terms of the amount of resource expended in order to achieve a goal (perhaps in terms of time to complete a task), and effectiveness could relate to the quality of this performance (perhaps in terms of the amount of activity completed or the quality of the outcome), and satisfaction would relate to the user perception of the activity (perhaps in terms of a judgment relating to their own performance or effort, perhaps relating to some aspect of using the device). What is required is not so much a battery of new measures, so much as an adaptation of existing approaches that pay particular attention to the relatively novel aspects of the environment and activity that pertain to mobile devices.

Making sense of human activity with mobile technology

The argument so far is that what needs to be evaluated is not simply the product, but the interaction between user, activity, device, and environment. This raises the question of what can be defined as appropriate forms of activity. The first issue for mobile technology is the assumption that it is to be used on the move, which raises two possibilities: (1) ‘on the move’ means physically moving, for example, walking, driving a car, traveling as a passenger; (2) ‘on the move’ means being in different places away from ‘normal’ office environments. One problem relating to both of these possibilities is the difficulty of collecting data in the field—there are problems arising from recording the data, managing the collection of data, and controlling experimental conditions that are far from trivial. However, if evaluation studies involve managing the interactions between user, activity, device, and environment, then it might not be possible to concentrate efforts on specific aspects of the interactions, for example, comparing the use of the device under different mobility conditions.

Interacting with mobile technology while walking

Consideration of interaction while moving immediately suggests that asking people to evaluate a product whilst sitting down in a laboratory might lead to different results than when using the product ‘on the move’. This is just what Kjeldskov and Stage (2004) demonstrated. Indeed, they found that having participants report usability problems while sitting down in the laboratory led to more usability problems being reported than when the participants performed the evaluation while walking. They suggested that this result might have arisen from different demands on attention—in the seated condition there was little distraction from the product and so participants were able to devote most of their attention to it, but in the walking conditions, attention needed to be divided between the device and the task of walking. This effect can be compounded by variation in other contextual factors, such as lighting levels and complexity of the path that one is following (Barnard et al., 2007).
It has been demonstrated that walking can impact cognitive tasks (Ebersbach et al., 1995), and so the use of a mobile device could be thought of in terms of a ‘dual-task’. A common methodological approach in Ergonomics/Human Factors involves asking participants to perform one task while attending to another, for example, tracking a line on a screen while also performing mental arithmetic. There are several reasons why this approach is useful, both in terms of developing theory of human performance and in terms of considering how combinations of tasks can be modified. In broad terms, the assumption is that the human ability to process information from several sources can be compromised under conditions of increasing complexity. Complexity might arise from the difficulty of one or both of the tasks, from the quality of the signals being attended to, from the amount of interference between the two tasks, and so forth. By measuring performance on the tasks under different levels of complexity, it is possible to judge the person’s ability to perform and the amount of interference that could occur.

Taking the dual-task paradigm as a starting point, one can consider many forms of mobile technology to be used not only in different places but also while the person is physically moving, for example, walking down a busy street or following a predefined route or walking on a treadmill. Thus, one approach to studying mobile technology from a dual-task perspective would involve measuring some aspect of walking and some aspect of using the technology. Barnard et al. (2005) compared reading tasks on a Personal Digital Assistant (PDA) while walking on a treadmill and walking along a defined path. They found a reduction in walking speed (by around 33%) compared to walking without performing the tasks on the device. This indicates that using the device leads to measurable changes in walking activity. They found no difference in comprehension between conditions (although it is often difficult to find measurable differences in comprehension in experiments that involve reading from screens, see Dillon, 1992), but they did find that word search took significantly longer when walking along the path than on the treadmill. This result suggests that participants walking the path had more need to divide their attention between the world and the device, and indeed, path following correlated with the use of scroll bars on the device, suggesting that more attention on the world led to more need to scroll the text to find one’s place while reading. What is interesting about this particular study is that it reports objective results on both primary (using the device) and secondary (walking under different conditions) tasks, and shows some interactions between the two. This shows that modifying the environment has a bearing on activity which, in turn, affects user performance (even with the same device requiring the same activity).

Using Mobile Technology while On-the-Move

Prototypical mobile technologies often address scenarios related to tourists because this emphasizes the need to move around an unfamiliar environment and the desire for information relating to the world around us, for example, routes to places, interesting information about landmarks, advice on traveling, and so forth. Considering the scenario from the perspective of usability, evaluation could allow the design team to agree on ‘benchmark’ levels of performance using existing practices, and to then consider what benefits might accrue from modifying those practices through the introduction of technology.

While the activity of walking can interact with the use of the mobile device, there are other aspects of use on-the-move that can also play a role. Duh et al. (2006) compared the evaluation of a mobile telephone, used to perform a set of activities, in the laboratory and on a Mass Rapid Transit (MRT) train in Singapore. The study showed that participants encountered significantly more problems in the train condition than in the laboratory. The authors relate the problem to five primary areas: ambient noise levels, movement of the train, issues relating to privacy, increase in effort needed to perform
Evaluating Mobile Human-Computer Interaction

the activity, additional stress, and nervousness. Of these factors, the main ones relate to aspects of the environment, viz. noise and movement of the train, and these, in turn, have a bearing on the ability of participants to complete the activity. In addition to the affect of movement on the performance of the users, the impact on the performance of the technology is equally important, for example, what happens when wireless networks do not cover the whole of the area and the user encounters ‘shadows’, or what happens when positioning systems have drift or inaccuracies. One approach might be to attempt to guarantee optimal delivery of service at all times by modifying the infrastructure rather than the device, for example, with boosters located in the environment. Another approach would be to provide ways of informing the user about accuracy of the data on which the system is working (Bell et al., 2006).

Devices can also be used while driving automobiles and there is evidence that interference between the activity of driving and the activity of using the device are more than simply physical (Boase et al., 1988; Brookhuis et al., 1991; Svenson & Patten, 2005; Wikman et al., 1998). This means that using a ‘hands-free’ kit will not eliminate all forms of interference. For example, Nunes and Recarte (2002) show that the more cognitively demanding a telephone conversation, the greater the reduction in the user’s ability to attend to the environment while driving. This research further highlights the problem of isolating the usability of the device itself from the interactions between user, activity, and environment.

**SUBJECTIVE EVALUATION OF TECHNOLOGY**

“[U]ltimately it is the users of a software system [or any product] who decide how easy its user interface is to manipulate…” (Holcomb & Tharp, 1991). Thus, one might feel that asking people about the product would be the obvious and most useful approach to take. However, there are several problems with this approach, for example, people might not always be able to articulate how they feel about the product (so the reports might be incomplete or inconsistent), people might use a variety of previous experiences as their referent models (so it might be difficult to generalize results across respondents), people might not be able to respond critically to the product (so there might be a ‘halo-effect’ with the participant responding to the novelty of the device rather than considering issues of usability). For these and other reasons, it is common practice to provide some structure to subjective evaluation, usually through some form of procedure or checklist. Furthermore, it would be suggested that subjective evaluation should be used as a secondary measure as far as practicable, with the primary focus on data collected from user trials.

**Subjective Response to the Device**

Participants could be asked to walk-through the performance of a given activity using the device, by explaining what they are doing and why. Monk et al. (1986) presented a detailed set of guidelines on how to use walk-through approaches to the evaluation in their Cooperative Evaluation method. The main aim of the approach is to capture problems that users experience when using a product.

In terms of checklists, a great deal of research effort from the late 1980s to the mid 1990s led to the development of a number of usability surveys. Some, like CUSI-Computer User Satisfaction Inventory (Kirakowski & Corbett, 1988) and QUIS-Questionnaire for User Interface Satisfaction (Chin et al., 1988), are designed to capture user response to an interface, particularly in terms of affective components (such as satisfaction). Others, like the checklist of Ravden and Johnson (1989) or SUS (Brooke, 1996), have been designed to cover both aspects of the interface and characteristics of usability. While these surveys are based on sound HCI principles, interpretation is left to the analyst who could lead to potential bias or misinterpreta-
tion. The SUMI checklist (Kirakowski, 1996) was developed using a rigorous approach to defining appropriate components of usability and presents results in terms of a comparison with a database of previous evaluations.

Subjective Responses to Using the Device To Perform an Activity

In addition to eliciting opinions from users regarding the device, researchers are also keen to obtain reactions of some of the consequences of using the device. By way of analogy, if we consider the virtual reality research community, we can see efforts to elicit reaction to either the physical effects of using virtual reality, for example, Cobb et al.’s (1999) Virtual Reality Induced Symptoms and Effects (VRISE) or the measurement of ‘presence’ (Slater et al., 1994; Witmer & Singer, 1998). In the domain of wearable computers, physical effects have been evaluated using self-report on a comfort rating scale (Knight et al., 2002).

In terms of performing an activity, researchers often make use of the NASA-TLX (Hart & Staveland, 1988) which measure subjective response to workload. The basic notion is that activities make different demands on people in terms of time pressure or mental effort, and can lead to different responses such as frustration or perceived level of performance. The NASA-TLX captures these responses and can be used to compare perceptions of users with combinations of different devices or activities.

DESIGNING AN EVALUATION PROTOCOL

Throughout this chapter, emphasis has been placed on the notion of ‘context of use’ and the concept of usability defined by ISO 9241, pt. 11. The relationship between these concepts is illustrated by Figure 1. In order to evaluate any item of technology, one needs to plan an appropriate campaign of evaluation—this means consideration of the evaluation from the start of the design process and performance of evaluation as often as practicable during the course of development. Assume that, whatever design process is being followed, there will be four primary phases: initial concept development, prototyping, specification and build. At each phase, the form and type of evaluation will change (depending on access to functionality on the product as much as anything else), but the basic considerations remain constant, that is, adequately defining context of use and applying appropriate usability metrics.

Figure 1. ISO9241 usability evaluation process
Before elaborating on Figure 1 as a process, it is worth re-emphasizing the point made earlier that usability evaluation always involves comparison with the product being considered against some referent model. The referent model could be other products, but is equally likely to be a set of design targets (see Table 2). In terms of comparison, a set of usability metrics can be applied. The ‘efficiency’ metric relates to the manner in which resources are applied during the activity in order to achieve the outcome; the ‘effectiveness’ metric relates to the completion of the outcome; the ‘satisfaction’ metric relates to the user’s response to performing the activity. Needless to say, all metrics apply to a given user performing a given activity in order to achieve a given goal in a given context of use with a given product. In terms of what to measure, each metric has several options. For the sake of brevity, in this chapter, one quantitative and one qualitative measure for each metric will be considered (the reader is encouraged to review ISO 9241, pt. 11 as a starting point for considering alternatives). For ‘efficiency’, a quantitative metric could be the number of mistakes a person made when using the product, and a qualitative metric could be a subjective workload (using the NASA-TLX mentioned); for ‘effectiveness’, a quantitative metric could be time to achieve the goal and a qualitative metric could be a subjective rating of performance; for ‘satisfaction’, a quantitative metric could be time spent using the device (over the course of several days) and a qualitative metric could be a self-report of how pleasant the product was to use. It should be apparent that the distinction between efficiency, effectiveness, and satisfaction is somewhat arbitrary, which is why it is important to make sure that all three metrics are applied during evaluation.

The idea that evaluation requires a ‘protocol’ is meant to imply that one ought to approach it in much the same way that one approaches the design of an experiment, that is, by defining independent variables, which are the goal, activity, and context of use, and by defining dependent variables, which are the usability metrics. The notion of the referent model also makes sense in terms of experimental design because the ‘hypothesis’ under test is that the outcome will be equal to or better than the referent model.

**Initial Concept Development**

During the ‘initial concept development’ phase, it is possible that one of the components of ‘context of use’ will dominate the others. For example, a designer might have an idea about how the product will function or how to perform a particular task or how to help a particular user. In order to explore this concept, designers make use of scenarios in various forms, for example, storyboarding, sketching, rich pictures, illustrative stories, and so forth. From Figure 1, it can be argued that a good scenario would include (as a minimum) some consideration of the type of person who would be likely to use the product, the tasks that the person would perform in order to achieve specific goals (as well as any other tasks that might need to be performed concurrently), the environment in which they might be performing these tasks, and the presence or use of other products to support this activity. In the domain of ‘traditional’ computer systems, the ‘environment’ can be assumed to be more or less constant, that is, the computer would be used on a desk in an office. In mobile computing, the ‘environment’ will have a significant impact on how the product will be used, as will the range of tasks that the person will be performing. It is this impact of the environment and the increasing range of concurrent tasks that makes evaluating mobile technology different from other computer applications. One way in which these aspects can be considered is to develop a scenario in which a person achieves the defined goal using no technology, another in which they use ‘contemporary’ technology and another in which they use the concept product. By storyboarding these different scenarios, the design team gets a feeling for the main benefits to be gained from using the product (and an
appreciation as to whether or not to pursue its development). During this stage, the usability metrics can be defined in terms of what measures can sensibly differentiate the product from any alternative ways of performing the task.

**Prototyping**

During ‘prototyping’ different versions of the product are developed and tested. The prototype need not be a fully-functioning product. Indeed, Nilsson et al. (2000) shows how very simple models can be used to elicit user responses and behaviors. Their study involved the development of a handheld device (the ‘pucketizer’ for use in water treatment plants and the initial studies had operators walking around the plant with a non-functioning object to simulate the device. From this experience, the design team went on to implement a functioning prototype based on an 8-bit microcontroller, wireless communications, and a host computer running a JAVA application). This work is interesting because it illustrates how embedding the evaluation process in the environment and incorporating representative end-users lead to insights for the design team. Taking this idea further, it is feasible for very early prototyping to be based on paper versions. For example, one might take the form factor of the intended device (say a piece of wood measuring 5” x 3” x ½”—which is approximately the size of Personal Digital Assistant) and then placing 3” x 2” paper ‘overlays’ to represent different screen states—change the ‘screens’ is then a matter of the user interacting with buttons on the ‘product’ and the evaluator making appropriate responses. Of course, this could be done just as easily using an application in WinCE (or through the use of a slideshow on the device), but the point is that initial concepts can be explored well before any code is written or any hardware built.

**Specification and Build**

‘Specification and build’ is the phase that one might traditionally associate with evaluation. Evaluation activity at this phase of the design process would be ‘summative’ (i.e., occur at the summation of the process), and would usually be used to confirm that the design was acceptable prior to committing to manufacture. At this stage, the main concerns regarding hardware and software would have been dealt with and so any usability evaluation that would call for significant change to hardware or software is likely to be ignored (unless the product is scrapped and the process started again, or unless these recommendations are filed for the next version of the product). However, usability evaluation can play an important role in this phase because it will form part of the acceptance testing of end-users and could, if positive, play a role in defining marketing activity or informing training requirements.

**CONCLUSION**

While the concept of usability as multi-faceted might seem straightforward, it raises difficult problems for the design team. The design team focuses its attention on the device, but the concept of usability used in this chapter implies that the device is only part of the equation and that other factors relating to the user and environment can play significant roles. The problem with this, of course, is that these factors lie outside the remit of the design team. One irony of this is that a well-designed device can ‘fail’ as the result of unanticipated activity, user characteristics, and environmental features.

The issue raised in this chapter is that evaluating mobile technology involves a clear appreciation of the concept of usability, in line with ISO standard definitions. The ISO9241 concept of usability emphasizes the need to clearly articulate the ‘context of use’ of the device, through consideration of user,
activity, device, and environment. This means that evaluation has to take account of the interactions between user, activity, device, and environment. What is essential is that evaluation is conducted in a way that ensures a good fit between the ‘context of use’ in the real-world and that simulated in the laboratory. This does not mean that one needs to include all aspects of the real-world in the laboratory but that one is able to reflect key variables and that the evaluation is designed to ensure a balanced comparison. It would be easy to ‘prove’ that a given device was superior to any other device simply by ensuring that the test favored the device in question. It is equally easy to ‘prove’ that evaluation in the ‘laboratory’ do not reflect performance in the ‘real-world’. However, such studies often reflect a limited grasp of adequate experimental design and, ultimately, a poor understanding of science. One is not ‘proving’ that a product is well designed through evaluation. Rather one is demonstrating ‘fitness-for-purpose’ under a well-defined context of use.

national Journal of Human-Computer Studies, 60, 599-620.

**KEY TERMS**

**Context of Use:** The combination of user, task, product, and environment during the achievement of a desired goal

**Dual-Task:** The performance of two (or more) tasks at the same time. This could involve simultaneous performance or could involve some form of time-sharing between the tasks.

**Effectiveness:** The ability of a given user to employ a given product to achieve a desired goal in a given context of use

**Efficiency:** The optimal expenditure of resources by a given user in using a given product to achieve a desired goal in a given context of use

**Referent Model:** A product (or set of metrics) against which a given product can be compared
Satisfaction: The subjective response of a user to interacting with a product

Usability: “... the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use.” (ISO9241-11, 1998)

Chapter 1.8
An Overview of Multimodal Interaction Techniques and Applications

Marie-Luce Bourguet
Queen Mary University of London, UK

INTRODUCTION

Desktop multimedia (multimedia personal computers) dates from the early 1970s. At that time, the enabling force behind multimedia was the emergence of the new digital technologies in the form of digital text, sound, animation, photography, and, more recently, video. Nowadays, multimedia systems mostly are concerned with the compression and transmission of data over networks, large capacity and miniaturized storage devices, and quality of services; however, what fundamentally characterizes a multimedia application is that it does not understand the data (sound, graphics, video, etc.) that it manipulates. In contrast, intelligent multimedia systems at the crossing of the artificial intelligence and multimedia disciplines gradually have gained the ability to understand, interpret, and generate data with respect to content.

Multimodal interfaces are a class of intelligent multimedia systems that make use of multiple and natural means of communication (modalities), such as speech, handwriting, gestures, and gaze, to support human-machine interaction. More specifically, the term modality describes human perception on one of the three following perception channels: visual, auditive, and tactile. Multimodality qualifies interactions that comprise more than one modality on either the input (from the human to the machine) or the output (from the machine to the human) and the use of more than one device on either side (e.g., microphone, camera, display, keyboard, mouse, pen, track ball, data glove). Some of the technologies used for implementing multimodal interaction come from speech processing and computer vision; for example, speech recognition, gaze tracking, recognition of facial expressions and gestures, perception of sounds for localization purposes, lip movement analysis (to improve speech rec-
An Overview of Multimodal Interaction Techniques and Applications

In 1980, the put-that-there system (Bolt, 1980) was developed at the Massachusetts Institute of Technology and was one of the first multimodal systems. In this system, users simultaneously could speak and point at a large-screen graphics display surface in order to manipulate simple shapes. In the 1990s, multimodal interfaces started to depart from the rather simple speech-and-point paradigm to integrate more powerful modalities such as pen gestures and handwriting input (Vo, 1996) or haptic output. Currently, multimodal interfaces have started to understand 3D hand gestures, body postures, and facial expressions (Ko, 2003), thanks to recent progress in computer vision techniques.

BACKGROUND

In this section, we briefly review the different types of modality combinations, the user benefits brought by multimodality, and multimodal software architectures.

Combinations of Modalities

Multimodality does not consist in the mere juxtaposition of several modalities in the user interface; it enables the synergistic use of different combinations of modalities. Modality combinations can take several forms (e.g., redundancy and complementarity) and fulfill several roles (e.g., disambiguation, support, and modulation).

Two modalities are said to be redundant when they convey the same information. Redundancy is well illustrated by speech and lip movements. The redundancy of signals can be used to increase the accuracy of signal recognition and the overall robustness of the interaction (Duchnowski, 1994).

Two modalities are said to be complementary when each of them conveys only part of a message but their integration results in a complete message. Complementarity allows for increased flexibility and efficiency, because a user can select the modality of communication that is the most appropriate for a given type of information.

Mutual disambiguation occurs when the integration of ambiguous messages results in the resolution of the ambiguity. Let us imagine a user pointing at two overlapped figures on a screen, a circle and a square, while saying “the square.” The gesture is ambiguous because of the overlap of the figures, and the speech also may be ambiguous if there is more than one square visible on the screen. However, the integration of these two signals yields a perfectly unambiguous message.

Support describes the role taken by one modality to enhance another modality that is said to be dominant; for example, speech often is accompanied by hand gestures that simply support the speech production and help to smooth the communication process.

Finally, modulation occurs when a message that is conveyed by one modality alters the content of a message conveyed by another modality. A person’s facial expression, for example, can greatly alter the meaning of the words he or she pronounces.

User Benefits

It is widely recognized that multimodal interfaces, when carefully designed and implemented, have the potential to greatly improve human–computer interaction, because they can be more intuitive, natural, efficient, and robust.

Flexibility is obtained when users can use the modality of their choice, which presupposes that the different modalities are equivalent (i.e., they can convey the same information). Increased robustness can result from the integration of redundant, complementary, or disambiguating inputs. A good example is that of visual speech recognition, where audio signals and visual signals are combined to increase the accuracy of speech
recognition. Naturalness results from the fact that the types of modalities implemented are close to the ones used in human-human communication (i.e., speech, gestures, facial expressions, etc.).

**Software Architectures**

In order to enable modality combinations in the user interface, adapted software architectures are needed. There are two fundamental types of multimodal software architectures, depending on the types of modalities. In feature level architectures, the integration of modalities is performed during the recognition process, whereas in semantic level architectures, each modality is processed or recognized independently of the others (Figure 1).

Feature-level architectures generally are considered appropriate for tightly related and synchronized modalities, such as speech and lip movements (Duchnowski et al., 1994). In this type of architecture, connectionist models can be used for processing modalities because of their good performance as pattern classifiers and because they easily can integrate heterogeneous features. However, a truly multimodal connectionist approach is dependent on the availability of multimodal training data, and such data currently is not available.

When the interdependency between modalities implies complementarity or disambiguation (e.g., speech and gesture inputs), information typically is integrated into semantic-level architectures (Nigay et al., 1995). In this type of architecture, the main approach for modality integration is based on the use of data structures called *frames*. Frames are used to represent meaning and knowledge and to merge information that results from different modality streams.

**MAIN ISSUES IN MULTIMODAL INTERACTION**

**Designing Multimodal Interaction**

Recent developments in recognition-based interaction technologies (e.g., speech and gesture recognition) have opened a myriad of new possibilities for the design and implementation of multimodal interfaces. However, designing systems that take advantage of these new interaction techniques are difficult. Our lack of understanding of how different modes of interaction can be combined best into the user interface often leads to interface designs with poor usability. Most studies to understand natural integration of communication modes are found in the experimental psychology research literature, but they tend to qualitatively describe human-to-human communication modes. Very few attempts have been made so far to qualitatively or quantitatively describe multimodal human-computer interaction (Bourguet, 1998; Nigay, 1995; Oviatt, 1997). Much more work is still needed in this area.

*Figure 1. Multimodal software architectures*
Implementing Multimodality

Developers still face major technical challenges for the implementation of multimodality, as indeed, the multimodal dimension of a user interface raises numerous challenges that are not present in more traditional interfaces (Bourguet, 2004). These challenges include the need to process inputs from different and heterogeneous streams; the coordination and integration of several communication channels (input modalities) that operate in parallel (modality fusion); the partition of information sets across several output modalities for the generation of efficient multimodal presentations (modality fission); dealing with uncertainty and recognition errors; and implementing distributed interfaces over networks (e.g., when speech and gesture recognition are performed on different processors). There is a general lack of appropriate tools to guide the design and implementation of multimodal interfaces.

Bourguet (2003a, 2003b) has proposed a simple framework, based on the finite state machine formalism, for describing multimodal interaction designs and for combining sets of user inputs of different modalities. The proposed framework can help designers in reasoning about synchronization patterns problems and testing interaction robustness.

Uncertainty in Multimodal Interfaces

Natural modalities of interaction, such as speech and gestures, typically rely on recognition-based technologies that are inherently error prone. Speech recognition systems, for example, are sensitive to vocabulary size, quality of audio signal, and variability of voice parameters (Halverson, 1999). Signal and noise separation also remains a major challenge in speech recognition technology, as current systems are extremely sensitive to background noise and to the presence of more than one speaker. In addition, slight changes in voice quality (due, for example, to the speaker having a cold) can significantly affect the performance of a recognizer, even after the user has trained it.

Several possible user strategies to prevent or correct recognition errors have been uncovered. Oviatt (2000) shows that in order to avoid recognition errors, users tend to spontaneously select the input mode they recognize as being the most robust for a certain type of content (modality selection strategy). When recognition errors occur, Suhm (2001) suggests that users be willing to repeat their input at least once, after which they will tend to switch to another modality (modality switching strategy). Finally, Oviat (2000) reports cases of linguistic adaptation, where users choose to reformulate their speech in the belief that it can influence error resolution—a word may be substituted for another, or a simpler syntactic structure may be chosen. Overall, much more research is still needed to increase the robustness of recognition-based modalities.

APPLICATIONS

Two applications of multimodal interaction are described.

Augmented Reality

Augmented reality is a new form of multimodal interface in which the user interacts with real-world objects and, at the same time, is given supplementary visual information about these objects (e.g., via a head mounted display). This supplementary information is context-dependent (i.e., it is drawn from the real objects and fitted to them). The virtual world is intended to complement the real world on which it is overlaid. Augmented reality makes use of the latest computer vision techniques and sensor technologies, cameras, and head-mounted displays. It has been demonstrated, for example, in a prototype to enhance medical surgery (Dubois, 1999).
Tangible Interfaces

People are good at sensing and manipulating physical objects, but these skills seldom are used in human-computer interaction. Tangible interfaces are multimodal interfaces that exploit the tactile modalities by giving physical form to digital information (Ishii, 1997). They implement physical objects, surfaces, and textures as tangible embodiments of digital information. The tangible query interface, for example, proposes a new means for querying relational databases through the manipulation of physical tokens on a series of sliding racks.

FUTURE TRENDS

Ubiquitous Computing

Ubiquitous computing describes a world from which the personal computer has disappeared and has been replaced by a multitude of wireless, small computing devices embodied in everyday objects (e.g., watches, clothes, or refrigerators). The emergence of these new devices has brought new challenges for human-computer interaction. A fundamentally new class of modalities has emerged—the so-called passive modalities—that corresponds to information that is automatically captured by the multimodal interface without any voluntary action from the user. Passive modalities complement the active modalities such as voice command or pen gestures.

Compared with desktop computers, the screens of ubiquitous computing devices are small or non-existent; small keyboards and touch panels are hard to use when on the move, and processing powers are limited. In response to this interaction challenge, new modalities of interaction (e.g., non-speech sounds) (Brewster, 1998) have been proposed, and the multimodal interaction research community has started to adapt traditional multimodal interaction techniques to the constraints of ubiquitous computing devices (Branco, 2001; Schaefer, 2003; Schneider, 2001).

CONCLUSION

Multimodal interfaces are a class of intelligent multimedia systems that extends the sensory-motor capabilities of computer systems to better match the natural communication means of human beings. As recognition-based technologies such as speech recognition and computer vision techniques continue to improve, multimodal interaction should become widespread and eventually may replace traditional styles of human-computer interaction (e.g., keyboard and mice). However, much research still is needed to better understand users’ multimodal behaviors in order to help designers and developers to build natural and robust multimodal interfaces. In particular, ubiquitous computing is a new important trend in computing that will necessitate the design of innovative and robust multimodal interfaces that will allow users to interact naturally with a multitude of embedded and invisible computing devices.

An Overview of Multimodal Interaction Techniques and Applications

KEY TERMS

Active Modality: Modality voluntarily and consciously used by users to issue a command to the computer; for example, a voice command or a pen gesture.

Feature-Level Architecture: In this type of architecture, modality fusion operates at a low level of modality processing. The recognition process in one modality can influence the recognition process in another modality. Feature-level architectures generally are considered appropriate for tightly related and synchronized modalities, such as speech and lip movements.

Haptic Output: Devices that produce a tactile or force output. Nearly all devices with tactile output have been developed for graphical or robotic applications.

Modality Fission: The partition of information sets across several modality outputs for the generation of efficient multimodal presentations.

Modality Fusion: Integration of several modality inputs in the multimodal architecture to reconstruct a user’s command.

Mutual Disambiguation: The phenomenon in which an input signal in one modality allows recovery from recognition error or ambiguity in a second signal in a different modality is called mutual disambiguation of input modes.

Passive Modality: Information that is captured automatically by the multimodal interface; for example, to track a user’s location via a microphone, a camera, or data sensors.

Semantic-Level Architecture: In semantic level architectures, modalities are integrated at higher levels of processing. Speech and gestures, for example, are recognized in parallel and independently. The results are stored in meaning representations that then are fused by the multimodal integration component.

Visual Speech Recognition: Computer vision techniques are used to extract information about the lips’ shape. This information is compared with information extracted from the speech acoustic signal to determine the most probable speech recognition output.

Chapter 1.9
Multimodal and Federated Interaction

Frankie James
SAP Research, USA

Rama Gurram
SAP Research, USA

ABSTRACT
This chapter introduces the concepts of multimodal and federated interaction. Because multimodality means, simply, the combination of multiple modalities (or types of input and output), the authors first introduce some of the various modalities available for computer interaction. The chapter then discusses how multimodality can be used both in desktop and mobile computing environments. The goal of the chapter is to familiarize scholars and researchers with the range of topics covered under the heading “multimodality” and suggest new areas of research around the combination of modalities, as well as the combination of mobile and stationary computing devices to improve usability.

THE BASICS OF MULTIMODALITY
As was discussed in the introduction to “Liability,” interaction with a computer (or computer-based device) can take place using a variety of different forms or modalities. On the input side, information can be transferred from a human operator to the computer via keyboards, keypads, touch screens, mice, joysticks, spoken language, or even gesture and motion sensors. Information can be output through visual displays (large and small), audio displays (including spoken text and non-speech sounds; see also “Mobile Speech Recognition”), and tactile displays (such as Braille or raised-line displays), as well as more exotic forms, such as force-feedback (haptic) joysticks and mice, and olfactory (“aroma-based”) displays.

Each of the input and output channels mentioned above have their own benefits and limita-
Multimodal and Federated Interaction

The purpose of this chapter is to discuss the concepts of multimodal interaction, where two or more modalities (such as vision or audio) are combined. Multimodal interaction is frequently used to compensate for limitations in one interaction modality by providing a second one. For example, the limited visual display capabilities of a mobile device can be augmented by providing audio output, or speech input can be provided to a user with limited typing ability to increase data entry speed. Multiple modalities can also be combined within a single input (or output) to increase efficiency; a seminal example here is the combination of a spoken action command (e.g., “color this red”) with mouse or touch-screen selection of the object to be acted upon. There are, of course, many other reasons for using multimodality, which will be discussed later in this chapter.

We will begin in this introduction with a discussion of the different forms of multimodality, as well as the different purposes to which multimodal interactions can be applied. In the next two sections, we address the use of multimodality for desktop applications and on mobile devices, where the reasons and methods for using multimodality can be quite different. We then discuss the concept of device federation, where multiple devices (each with their own available modalities) can be combined within a single interaction. Finally, we conclude with the chapter summary.

DIFFERENT FORMS

The basic definition of multimodality is the use of more than one modality within a single interface. The availability of both keyboard and voice input is one of the most common examples of multimodality, as is the use of both visual (text or graphical) and audio output. Most of the five classical human senses (sight, hearing, touch, smell, and taste) can be used for both the input and output sides. Each sense allows a broad range of possibilities.

Table 1 gives a brief list of the types of input and output that are associated with the senses. The most common use of the sense of sight is in the visual presentation (output) of information on small and large displays. Sight can also be used for input: eye tracking can be used for selection or to gauge interest in a particular area of a screen, and retinal scanning can be used to identify the user.

Input options based on the sense of hearing include speech, for entering text or giving commands, speaker identification (to identify or authenticate the user), and even humming (Ghias et al., 1995). Audio output can be used for presenting written text (using text-to-speech), recorded audio files, document and interface structures, and sonifications of graph data [see the chapter “Mobile Speech Recognition” and James (1998) for an overview]. Speech input and audio-based output are useful in a variety of contexts, including mobile and vehicle-based scenarios, as well as accessibility.

The sense of touch is already commonly found in computer inputs today, through the use of keyboards, pointing devices, and touch screens. In addition to detecting simply that a key, button, or screen area has been clicked or touched, more advanced devices (such as game controllers and track pads) can also detect the amount of pressure exerted by the user. Handwriting and gesture are also gaining in popularity within certain contexts, along with the use of fingerprints for user iden-
Multimodal and Federated Interaction

In the near future, we can expect to see heat and motion-sensing inputs, possibly for tracking people and objects. Tactile and haptic displays are also used for output, especially to make computers accessible to disabled users. Tactile displays include Braille and raised-line displays, which can be felt with the fingertips or hands to recognize shapes and text. Haptic displays use force feedback, generally to the hands and fingers, to present textures and boundaries that represent elements within the user interaction.

Smell and taste have spawned the creation of some new output possibilities, including the intriguing, if somewhat irreverent, Edible Bits (Maynes-Aminzade, 2005) gustatory display. The applicability of these senses to human-computer interaction, however, appears to be limited to specialized applications and artistic contexts.

Multimodal applications differ in which modalities and techniques they choose to combine, as well as in the ways that the modalities are used together. Some applications use modalities in a redundant way, so that input can be given in any of the available modalities, and the same output is rendered simultaneously in multiple modalities. Other applications use the modalities to complement one another, combining multiple inputs or outputs to produce a single command or piece of output (also called multimodal fusion). The choice of whether to use redundant or complementary modalities is dependent on the goals, context of use, and target user group for the application. Examples and use cases for both of these methods are described below.

**DIFFERENT PURPOSES**

Applications are designed to use multimodal interactions for a wide variety of reasons. Having several modalities available can allow designers to create applications that are easier or more natural to use, or that can be used by more users within more contexts. Table 2 shows the different purposes of using multimodality, categorized by

the way the modalities are combined in the interaction. In many cases, the purposes are valid both for mobile and non-mobile (i.e., desktop) devices; in other cases, there is special value in using multimodality for specific device categories.

The most common usage of complementary modalities (or multimodal fusion) is to attempt to make the interaction more natural, where modalities are chosen that are the best fit to different parts of the task. For example, pointing and other gestures are appropriate for selection, while voice may be more efficient for entering text. Complementary modalities can also be used to spread the input or output across different modalities, reducing the load on any one channel. One example here is on the output side, where the most important or urgent information is presented in audio while supporting information is presented visually. The benefit is that the user can get both the key and supporting information simultaneously by listening to the audio and attending to the visuals at the same time.

Replacement modalities, as the name implies, replace one modality for another. Replacement can produce a more natural interaction, when, for example, keyboard entry of a password is replaced by speaker identification in a system that already allows voice input. On a mobile device, replacement can also be used to compensate for the limited capabilities of the device—long portions of text output are difficult to read and scroll through on a small screen, and may be easier to comprehend using an audio presentation.

Redundant modalities provide users with the ability to choose from different interaction options. By allowing both voice and keyboard input, for example, an application is more accessible to users who can’t type well or who have a physical disability. Redundant output, presented both visually and auditorially, can benefit not only users with visual disabilities, but also users performing tasks requiring their visual attention to be focused elsewhere (for example, while driving). The remainder of this chapter presents these purposes in more detail within the context of example applications and research prototypes.

MULTIMODALITY ON THE DESKTOP

Because desktop computers are still the primary computing environment for most users, we begin our discussion of multimodality on this platform. People frequently see multimodality as unnecessary or even inadvisable on desktop computers—“I don’t want to talk to my computer, or have it talk back to me, in my office…someone might hear some of my private information!” This section will show that there are many cases...
where the uses of multimodal input or output (even speech and audio) are indeed very useful tools for desktop interaction.

In desktop settings, there are several uses of multimodality:

1. To make the interaction more natural, by mapping information to be input or output to the most appropriate modality;
2. To provide better and more usable security;
3. To increase accessibility for disabled users.

This section discusses each of these uses, and concludes with the presentation of an area of possible research around the use of multimodal output in desktop computing.

**Using Multimodality to Make Interaction More Natural**

Standard desktop systems use keyboard and mouse for input, with visual displays and some (limited) audio output. For many interactions, these tools and modalities are appropriate; for example, selecting an icon on a desktop or some text in a document is straightforward using a mouse or other pointing device. However, other interactions involving pointing devices require far more effort on the part of the user, when the mapping requires users to search long menus or complicated tool bars for desired commands (for example, when specifying the attributes of a shape or icon placed on a canvas). Keyboards, while useful for entering text into a document, are not as useful for issuing commands or entering passwords, where arcane syntax and structures must be remembered. By providing more input modalities to a desktop computer user, interactions can be optimized to be more natural, and may also reduce the amount of visual clutter on the display.

Speech is perhaps the most commonly available input modality after keyboards and pointing devices (although as Oviatt [1999] points out, it should by no means be considered the primary information carrying modality within a multimodal system). Speech recognition systems use grammars to define the commands or phrases that can be accepted by the system. Speech recognition grammars can range from types found in standard computer theory (regular grammars, context-free grammars) to statistical grammars (e.g., n-gram grammars, where the system uses the preceding n-1 words spoken by the user to help identify the n-th word).

**Replacement Modalities**

Within the desktop context, speech input can be used to make an interaction more natural and also more visually appealing, by eliminating the need to display complicated tool bars and menus. A striking example of this is the CommandTalk system, which enabled users to create, control, and modify battlefield missions and control the map display of the ModSAF battlefield system using spoken language and mouse input (Moore et al., 1997). Through the addition of the CommandTalk speech interface, the researchers were able to reduce the screen clutter of ModSAF, eliminating almost all of the tool bars that had previously been required for specifying details of checkpoints and ordinances, controlling the display, and specifying mission movements.

The architecture of CommandTalk included many natural language processing components to create an intuitive command language. The speech recognition grammar was designed to allow the same commands and object referents as would be used in a human-to-human interaction. Complications regarding the resolution of noun phrases (“the M1 platoon”) to specific units shown on the display, and the mapping of predicates to interface actions (“move,” which can map to one of two different commands depending on
the type of platoon to be moved) were handled automatically and made transparent to the user. By designing the grammar using a corpus of sample human-to-human dialogues, the interaction is made extremely natural for users who already understand the domain, and the system can be used without much initial training.

In CommandTalk, the spoken language interface provides an alternative means of input. CommandTalk also changed the visual display of the underlying application, although this is not strictly necessary when creating a multimodal version of an existing application. The available input modality, speech, was in this case used as a replacement modality. Replacing one modality with another should, however, be done with caution. The spoken language input for CommandTalk was designed to be natural for expert users in the domain, based on sample dialogues. Non-expert users who are unfamiliar with the domain will require some time to learn the command structure that is used for the task. Toolbars and buttons can act as visible reminders of the available commands—these reminders allow users (especially non-experts) to build up their understanding of the domain using recognition memory. Removing the visible reminders forces users to rely on recall memory (Lodding, 1982).

In multimodal systems designed for non-expert users, it may be more appropriate in many cases to add a new modality without removing the old; in this case, the speech input would have been a redundant modality.

Complementary Modalities

Input modalities can also be used in a complementary way, where the inputs from several modalities are fused to produce a single input command. This is commonly known as multimodal fusion. Multimodal fusion allows users to mix and match modalities as they choose, and the system attempts to find a coherent meaning for the set of inputs. For example, when speech and gesture input are combined, spoken commands can be used to specify actions, while mouse or pen gestures specify the objects or action details. This can be much more efficient or more usable than using the mouse to both select the object and the command, since the two parts can be done simultaneously and because the user does not have to search the visual menus or tool bars for the command. Combining voice and a pointing device is also more natural than using voice alone, since object selection and many other tasks (such as resizing and moving) can be tedious and error-prone to accomplish using voice alone (see, for example, the Voice-Enabled Portal project, described later) (Grasso et al., 1998; Tyfa & Howes, 2000).

Many multimodal fusion systems focus on the use of speech with other modalities. One of the first systems to combine voice and gesture was the “Put-That-There” system (Bolt, 1980). The system focused on the basic concept of combining voice and gesture into what Bolt called a “concerted, natural user modality.” The system allowed users to place shapes on a large screen display, when seated facing the screen. Gesture sensors were used to determine the placement of the shape, while speech commands gave additional information, including the type of shape, color, and size. The gestures disambiguated deictic references (references whose interpretation is relative to the context of the utterance) in the spoken commands, such as “that” and “there.” As Oviatt (1999) points out, deictic commands tend to dominate multimodal input, since they are also widely used in human-to-human communication.

The combination of speech with gestures has most commonly been demonstrated in map-related tasks. Koons et al. (1993) describe a system that integrates speech, gesture, and eye gaze input to query objects on a map. Their focus is on the interpretation of multimodal commands from the three modalities, using reasoning to combine the modalities and determine the objects and actions requested. The Multimodal Maps application designed by Adam Cheyer and Luc Julia (Cheyer

...
Multimodal and Federated Interaction

& Julia, 1998) is another example of a system that fuses gesture and voice inputs to produce a natural, less error-prone application (their paper is also a good reference to other publications related to multimodal fusion). The application is a travel planning tool that shows locations of interest on a map display. Users can ask questions using either modality, or both in combination. For example, users can give the spoken command “show restaurants within one mile of this hotel,” specifying the hotel by circling it on the map.

Multimodal commands involving speech can be formed and used in a variety of ways, and systems built to understand them have to be able to handle these differences. For example, while some commands may be formed by actions that co-occur, such as a circling gesture or pointing action that occurs simultaneously with the speech, many commands that should be combined are temporally separated: the gesture or pointing action may occur either before or after the spoken command. It is extremely important to properly associate the actions, since the information given in the spoken command may be impossible to fully interpret without the gesture, and vice versa. Standard algorithms pay attention to the temporal ordering of actions in various modalities, evaluating whether two actions are related based on how long the “gap” is between the actions, whether the individual actions themselves can be well-formed commands, and other criteria. Even systems that are designed with multimodal fusion in mind must be able to support unimodal commands (independent gestures or speech), since users typically intermix unimodal and multimodal commands (Oviatt, 1999).

Multimodality and Security

Computer security and usability often find themselves in conflict. For example, computer security suggests that user passwords should contain digits, non-alphanumeric characters, be more than six characters long, and not listed in a standard dictionary. Usability findings suggest that passwords that conform to these rules will be difficult to remember, causing users to compromise security by writing the passwords down for future reference. New modalities, in the form of biometrics and other techniques, may provide a solution to this problem.

Biometric identification systems include speaker identification, fingerprint recognition, and retinal scanning. These systems rely on obtaining a unique identifier for a user that is based on who the user is. In addition to reducing the need for users to remember an arcane security code, biometric identification can make a system easier to use by combining the identification task with other interaction tasks. For example, voice identification could theoretically be done while the user is giving a voice interaction command. The user experience is that the extra identification step is being “skipped,” when in fact it is being processed in the background.

Because current biometric identification systems are not 100% accurate, identifiers based on what the user knows (similar to passwords) will likely continue to be part of computer security. Multimodal techniques in this category include picture recognition tasks, where users must identify a familiar picture from among a set of unfamiliar ones (Weinshall & Kirkpatrick, 2004). Other applications are beginning to emerge within the picture recognition space, such as the SiteKey feature of the Bank of America website, where users select a picture to be displayed after they have logged in to online banking. The display of the user-selected picture reassures users that the pages and information they are viewing indeed come from the bank. Interestingly, decades-old research (Bakst, 1988) suggests that the best computer security will require a combination of who the user is, what the user knows, and something the user carries (for example, a keycard). By definition, a system that includes all of these would have to be multimodal.
Multimodality and Accessibility

New, often redundant, modalities can be added to an application to simply provide an alternative means to enter or receive information. One of the major reasons for doing this is to support the goal of accessibility, where computer systems are made to be usable by people with disabilities. By providing speech input capabilities, for example, users with physical disabilities that affect their ability to type or handle a pointing device can have access to the same applications that non-disabled users do. Similarly, audio (both speech and non-speech) output can be provided in addition to a visual screen to make an application or system accessible to blind users.

Accessible applications can be created in several ways, depending on when in the design process the issue is considered and the function of the application. Table 3 gives an overview of approaches that can be taken to make an application accessible, and lists benefits and drawbacks for each approach.

If accessibility is considered early in the process and a design is created that incorporates multiple input and output options to support a wide range of users, this is an example of *universal design.* Although there is some argument about whether it is in fact possible to create a design that is universally usable (Mace, 1998), especially given the difference between input modes and the kinds of information that they can most easily express (Oviatt, 1999), universal design is frequently applied to systems that are to be used in a public context. Legislation regarding equal accessibility to information (such as the Americans with Disabilities Act and Section 508 of the Rehabilitation Act in the United States) encourage the designers of kiosks, automated teller machines (ATMs), and other public computing sources to take this approach.

Some applications are designed early on to be accessible, but with a focus on a specific group of users. For example, several commercial systems and research projects [such as pwWebSpeak, ASTeR (Raman, 1993), and AHA (James, 1998)] have addressed the issue of giving blind users better access to WWW-based content, taking different approaches to presenting structured documents in audio. One of the interesting things about this area of research is that the underlying WWW documents are not altered, but are instead interpreted differently by the new application to achieve accessibility.

</table>
Accessibility can also be added to products later on, as in the case of voice-enabled portal. The voice-enabled portal (VEP) [originally called “Voice over Workplace” in James & Roelands (2002)] is another example of a speech interface that was developed as a redundant means of input for an application, in this case a business portal. The system was designed to support physically disabled users by adding speech capabilities to multiple applications within a portal, without requiring those applications to be changed. To do this, the VEP interface supported navigation and basic text entry based on the application’s syntax. Users selected items by speaking their names or by referring to elements by their type (e.g., “text box”). A major problem for this system was in disambiguating commands that could refer to multiple targets: if there are four text boxes on the screen, to which one does the command “text box” refer? Because the main goal was to provide access for physically disabled users, the solution chosen uses voice input exclusively: VEP used a predefined prioritization scheme to prioritize targets based on their location on the screen, choosing the target with the highest priority. If more than one target had equally high priorities, VEP numbered the targets using semi-transparent icons and required the user to specify the desired one.

Screen readers are another type of application where accessibility is added after an application has already been designed and built. Screen readers give blind users access to graphical interfaces using audio feedback and text-to-speech systems to read back text on menus, within open documents, and related to icons. These systems typically use access “hooks” provided by the applications and the operating system to find text, icons, and other graphical elements. For physically disabled users, third-party speech recognition systems (as well as those offered by the operating systems vendors themselves) also use the “hooks” to generate command grammars that allow users to control applications as well as enter text.

Accessibility and design for users with disabilities may seem like a specialized area of work, with a relatively small target population. However, as pointed out in Perry et al. (1997) and other sources, users can be handicapped, or unable to accomplish a task, merely because of the circumstances in which they try to perform it. So-called temporary disabilities, such as the inability of a user to direct his visual attention to a computer monitor, can be mitigated through the use of alternative modalities.

Multimodal Output and Transferring Tasks between Modalities

Much of this section has focused on the use of multimodal input in desktop settings. Multimodal output can also be used in desktop computing, especially for accessibility, as in the example of screen readers for blind users. Another potential use for multimodal output in a desktop setting is related to computing tasks that may be continued in a non-desktop setting, such as reading and reviewing documents while mobile.

Imagine the case where a sales representative is in her office reviewing her previous interactions with a client whom she will be visiting later that day. She reads through meeting minutes, e-mails, and other text-based documents to refresh her understanding of the situation. At the meeting that afternoon, the client says something that reminds the sales representative of a note in one of the documents she read, so she wants to go back to the document to get more details. Because the sales representative is out of her office, she is only carrying a mobile device, which does not have a large enough screen to display the document. The device is, however, capable of presenting the information via an audio interface. Will an audio review of information that had been previously only viewed visually be as helpful as a reminder as would a visual glance?

The intriguing question rising from this and similar scenarios is based on the concept of source
memory (Johnson et al., 1993), or the memory of the qualities of the information presented (e.g., was it spoken or read, who said it, was it new information, etc.). If information is presented in one modality, but then must be retrieved using a different modality, does this affect the user’s success rate, efficiency, and other retrieval factors? If research shows the answer to be yes, it may turn out to be beneficial to support additional output modalities (e.g., speech and audio) in a desktop computing environment. Information can initially be presented in several modalities simultaneously, so that later review or search in any of the modalities is made easier.

**MULTIMODALITY FOR MOBILE DEVICES**

Increasingly, computer usage is moving from desktop-based systems towards mobile devices, including personal digital assistants (PDAs) and mobile smart phones. New business and consumer applications for mobile devices are being created on an almost daily basis, to provide services and information to mobile users. However, the design of mobile applications presents many challenges from the standpoint of usability.

Mobile devices are limited by their very nature in terms of the user experience they can provide. In order to remain portable, mobile devices are constrained to a small form factor, which means that their input and output devices are also small. Tiny keypads and touch screens make input a challenge, especially when the user is walking or moving through the world. Small output screens are difficult to read and cannot present much information at one time. This section describes how multimodal input and output support can enhance the usability of mobile devices.

**Input Modalities for Mobile Devices**

Mobile devices come in several varieties, two of the most common being PDAs and mobile phones. The default input for these two device groups differs: mobile phones typically use a keypad (usually a 12-button telephone keypad, with perhaps a few additional function buttons), whereas PDAs (especially consumer-based models) as well as certain smart phones (for example, the Palm-based Handspring series) typically rely on handwriting input on a pressure-sensitive screen or small keyboards. It is interesting to note that although phones were originally designed to facilitate voice communication, interaction with mobile phone devices for tasks other than talking to another person (e.g., messaging, changing settings, and dialing) still rely heavily on non-speech input and output.

The small keypads used by most mobile phones make it difficult for the user to efficiently enter text and perform other input functions. Telephone keypad mappings requiring multi-tap or predictive text entry can be error-prone and add additional steps to the user interaction. QWERTY keyboards on mobile devices are so small that the buttons can be difficult to accurately select. Initial attempts to mitigate these problems were taken by the device manufacturers themselves: PDA designers offered external keyboards that could be attached to the devices. The problem with this solution, as well as related research into keyboards that can be projected on a tabletop, is that keyboards are difficult (if not impossible) to use while standing, walking, or moving. If the user is forced to sit and remain stationary to use the keyboard, it defeats much of the purpose of the mobile device.

Keyboard alternatives have been proposed for mobile and wearable device input. These include a variety of gesture-sensing devices, such as the FingeRing device (Fukumoto & Tonomura, 1997), which senses chord-style typing using a set of wearable rings. Chord typing is based on
particular combinations of fingers tapped on a surface simultaneously; for example, tapping a combination (or “chord”) of index, middle, and ring finger describes a single letter of input. FingeRing allows users to tap chords on any surface, including a leg or arm, making it more useful while walking or moving. Other chord keyboards, such as the Twiddler©, are small hand-held devices with strategically placed keys that can be selected in groups to form the chords. The limitations of chording, though, are a small input alphabet (for FingeRing: five fingers, with two positions each per chord, yields only 32 different chords) and a fairly high cost of learning effort.

On the PDA side, handwriting recognition via stylus has been available since the early days of the Apple Newton. Unfortunately, problems with the quality of the recognition using this system were at least partially responsible for the device’s demise. More recently, the Graffiti system offered with Palm devices has seen better success, with its stroke-based (rather than word-based) recognition. Although Graffiti (or, rather, the underlying Unistrokes alphabet) was specifically designed to minimize recognition errors, Shneiderman (2002) also attributes the success of Graffiti to the ability of users to more easily see the locality and cause of errors than with word-based recognition.

Stylus input, then, seems to be a fairly good input modality for small devices. However, stylus, as well as the small keyboards found on Blackberry-style devices, face limitations in many mobile settings. These include situations where the user’s hands are busy or encumbered by gloves, or where the user’s eyes are busy. Both the stroke-based recognition used by Graffiti and small keyboards can be a bit slow and rather cumbersome for entering large amounts of text. Other modalities, such as voice, can alleviate some of these problems.

Voice input is a common and well-accepted alternative to stylus or keypad input for mobile devices. (“A Conversation with Jordan Cohen,” 2006) Mobile phones are especially well adapted to voice input, given that they already contain a microphone to support the telephony functions of the device. Voice input can free up the user’s hands to perform the other functions necessary when mobile, such as carrying packages, opening doors, steering a car, or wearing gloves. Of course, voice input has its limitations in a mobile context, as well. In extremely noisy environments, recognition quality can deteriorate to the point that voice is unusable. Quieter environments may also be problematic for voice input, when it is inappropriate to talk or when it would be undesirable to be overheard. Technologically speaking, speech recognition via mobile phone often has a higher error rate than desktop-based recognition, both due to potential background noise and the quality of the device’s microphone. And, limitations in device memory can force speech recognition grammars to be quite small, which impacts usability.

Another way to improve user input to a mobile device is to eliminate or reduce the need for the input. With new capabilities to determine the location of mobile phones, such as global positioning systems (GPS) and cell towers, mobile devices can automatically gather information that would otherwise require human input. For example, if a user conducts a search for restaurants, he is likely to want to find a restaurant close by. With an application that is not context-aware, the search query needed for this task will be something like “restaurant Palo Alto.” If the device is able to detect the user’s location, the query from the user would only have to be “restaurant,” and the application could use the device’s location to filter the results.

Context-awareness can be used in even more clever ways, as well. The MICA (Multimodal Interaction in Context-Adaptive Systems) project used context awareness to sense actions by the user that could be used as inputs (Lorenz et al., 2005). The warehouse-based prototype designed in the MICA project can sense when the user was passing an item that needed to be picked from a
shelf and placed on the user’s trolley, and indicate this to the user. In addition, the system was able to recognize when the user was looking for, but unable to find, an object on a shelf and provide guidance to the exact location.

Finally, mobile device input can be augmented using technologies that sense movements (e.g., tilting or lateral motion) of the device itself (Hinckley et al., 2005). For example, a phone can detect when it has been picked up and placed by the user’s ear to automatically activate the speaker. Or, a device can detect that it has been tilted, to scroll down on a menu. Such interactions can be achieved by augmenting the device with rotational and gyroscopic sensors, or by new techniques that make use of mobile phone cameras (Wang & Canny, 2006).

Output Modalities for Mobile Devices

The small screens available on mobile devices are not really adequate to display all of the complex information that is requested by mobile users, such as maps, directions, and documents. The most common way of addressing this is through the use of audio output to augment the small-screen display. For example, many navigation systems show a small portion of a map view on the phone screen, with turn-by-turn directions presented using voice. This type of interaction also benefits mobile users by allowing them to focus more of their visual attention on locomotion tasks, such as walking and driving, which are common when using mobile devices. The next section goes into more detail on the use of audio output in divided attention scenarios.

Mobile devices can also make use of haptic feedback as an output modality. The canonical example here is a vibration alert on a mobile phone. These alerts do not require either visual or auditory attention, making them useful in very noisy or very quiet environments while the user is mobile. Haptic feedback can be used in mobile applications, such as navigation, to support the movement-based input described above (e.g., tilting and rotation). Haptic output can provide the user with more feedback and control during tilting input, for example, by providing some level of resistance to help the user’s actions stay in sync with the action taken on the visual display (Oakley & O’Modhrain, 2005). More experimental uses of haptics include the expression of presence by a remote participant to enhance social interaction [for example, Rovers & van Essen (2004) and Teh et al. (2006), where hand-holding, petting, or hugging by the remote participant is expressed to the user through vibration on the local device].

Designing for Divided Attention

As mentioned above, mobile devices are used in many contexts where the user is unable to devote his or her full attention to the mobile device interface. These contexts include device interaction while walking or driving: situations where the mobile device task is secondary, and the task of locomotion or navigation through the world is primary. The user’s attention must be divided between the primary and secondary task, and the mobile device interaction must be sensitive to the fact that it is secondary. This means that the interaction must be designed to be usable without requiring undue amounts of attention, and must be especially sensitive to the modalities used to avoid overloading any of the sensory channels.

Multimodality can be used effectively in divided attention situations, most frequently by providing information input and output capabilities on channels that are not as important to the primary task. For example, visual attention requirements can be reduced by providing redundant output using the audio channel. This also reduces the need for the user to be in close physical proximity with the device, since audio can be heard over a greater distance than small visual displays can be used. Prototypes for warehouse picking have been designed in this way: the MICA system, for example, provides redundant visual and audio
information so that the worker can move away from the visual display on the warehouse trolley to retrieve an item from the shelf, while still receiving information about the item to retrieve (Lorenz et al., 2005).

An important caveat, however, is that simply changing modality does not always produce an interaction that can be used effectively in divided-attention scenarios, especially vehicle-based scenarios. A study on speech-based interaction in a driving context showed that menu navigation produced competition for attentional resources with the spatial aspects of navigating the vehicle (Lee et al., 2001). The central processing theory of attention suggests that this is because central resources are being overloaded, even if none of the individual modalities are (Moray, 1999). Therefore, divided-attention interactions should also be careful about the sheer amount of information that is to be presented, perhaps by adapting to the current driving situation based on information about traffic conditions, driver stress, and so forth.

Finally, investigations of vehicle interfaces have shown that the style of information presentation has a strong impact on driving ability. Lee et al. (1999) found that drivers responded differently, in terms of response time and action taken, depending on several factors. These factors included not only modality, but also display location and message style (e.g., whether the system advised of a situation or gave explicit instructions for action). Other studies have also shown that the phrasing of messages, as well as the emotions expressed by the voice used for output, have an impact on driving performance and attention (Jonsson et al., 2004; Jonsson et al., 2005). Voice gender can also make a difference, especially for certain tasks such as navigation and feedback on driving performance (Nass & Braves, 2005).

**DEVICE FEDERATION**

An emerging area of research in human-computer interaction involves the combination of small, portable devices with ambient computing and interaction resources in the user’s environment. This concept, which is cropping up in industrial and academic research projects at various locations, is an attempt to balance the dual problems of portability and usability through a new model for mobile interaction, which we will call here **device federation**.

The idea of device federation is to augment small, portable devices such as smart phones (called personal devices) with ambient computing resources, such as large displays, printers, computers, PDAs, and keyboards. The personal device can be used to establish the user’s identity (see the discussion above related to improving security by combining something the user carries with what the user knows and who the user is), run applications, or connect to back-end databases and servers, while ambient resources are leveraged to provide usable input and output. Conversely, personal devices can be connected to external sensors that have minimal or no user interfaces of their own, allowing the user to view or manipulate data that would otherwise be hidden within the environment.

Device federation is a broad concept, which covers a wide range of federation types. An obvious example is federating large displays with small mobile devices. Other types include federating sensors and other resources with limited human interaction capabilities with mobile devices, federating portable user devices with audio output, and federating portable input devices with ambient computers to provide accessibility.

**Ad Hoc Wireless Federation**

Device federation promises the ability to augment the large amount of computing resources found in today’s portable devices using the ambient devices
Multimodal and Federated Interaction

found nearly everywhere in the Western world. More and more offices, coffee shops, airports, and other locations contain large displays, speakers, and keyboards that could be used to make up for the limited input and output capabilities of mobile devices. Within the context of business usage, goals include allowing users to federate keyboards or other input devices with a personal mobile device to enhance input, or allowing voice input through a mobile device to be recognized and sent to a federated large-screen display.

It is already possible today to connect input and output devices to mobile phones and PDAs. USB and other wired connections provide a standard interface for keyboards, mice, displays, and other devices to connect to personal devices in a fairly seamless manner. However, wired connections require device proximity, which can be problematic for some use cases, such as connecting a mobile phone to a large-screen display. It would be preferable to be able to connect to the display from anywhere in the room, without having to be right next to it. In addition, some phones may not have standard wired connection points and instead use proprietary ports and connectors. Therefore, device federation holds wireless connectivity as one of its main goals.

The second main goal of device federation is to allow ad hoc connectivity. Many common wireless standards, such as Bluetooth, use handshaking and pairing protocols that are far too cumbersome to be of value when a personal device is to be connected to a particular ambient resource only once or twice in its lifetime. These protocols are also not very user-friendly, especially for inexperienced users.

One concern regarding ad hoc wireless federation is, of course, security. Devices that can easily connect and disconnect can also be easily compromised. Unfriendly devices could be used to snoop on data connections, or to grab computing resources. However, the need for security must be balanced with usability, so that the benefits of federation are not compromised.

Input and Output Federation

One of the most basic scenarios for device federation is display federation. Mobile devices often have screens that are too small to adequately display information, especially if the information involves complicated visualizations, graphics, or large quantities of text. Output federation can solve this problem by connecting with a nearby display to present the information. Additionally, input mechanisms to large screen displays have been investigated by many research groups [see Bezerianos & Balakrishnan (2005) for a recent example]. Federation offers another alternative, by allowing input through a mobile device to control a large-screen display.

The implementation of display federation is not as future reaching as it may seem. Intel's Ubiquity project is currently prototyping a device called the “Personal Server,” which could be used for this purpose. The personal server is “a small lightweight computer with high-density data storage capability.” The primary purpose of the device is to store data and provide computing power that can be leveraged by other devices (such as a laptop, desktop, or projection displays) using a local wireless connection (Want et al., 2002). In fact, some of the original incarnations of the Personal Server have included no direct input and output capabilities: the very use of this device depends on display federation (as well as federation to input devices). WinCuts from Microsoft Research allows users to push shared areas of live screen content to other machines, which are controlled locally (Tan et al., 2004). PdaReach by June Fabrics displays the contents of a PDA screen on a computer connected via the PDA synchronization cable.

What remains to be investigated are usage scenarios and design for display federation. For example, should all content automatically be routed to a federated large display, or should users explicitly control the portions of the output to be
displayed? Such considerations likely depend on the applications involved, the security or privacy of the environment, and other factors.

The federation of input devices would allow users to federate the input devices of their choice with other resources. Users could, for example, federate a speech input device to a computer, thereby allowing multimodal input to the computer’s applications. This would not only be beneficial to mobile users, but was also proposed more than ten years ago as a solution to the accessibility problem (Perry et al., 1997). The basic idea was to provide users with a portable device that exactly met their needs in terms of input capabilities: low-mobility users could use single-switch or voice entry, blind users could use Braille entry devices, and so forth. This would be an example of creating a “helper application” to support disabled users (as discussed earlier in this chapter): the new element here is that the helper application would not need to reside on the same computer as the original application.

The Apple iPod is also a good example of input federation. The iPod is portable and allows self-contained functionality, but its input and output functionality increase when federated with other devices such as computers and car stereos. Federation with car stereos is especially interesting in regards to the distribution of I/O: some products federate the iPod to a car stereo’s speakers, handling input via the iPod itself, while others use the car’s output and input. User satisfaction with the different products can provide insight into federation for other consumer or business applications.

Because flexible connection and disconnection is a goal for device federation, it is possible that users may want to federate (or de-federate) within the course of performing a task. This again raises the possibility of using redundant outputs to facilitate task transfer, as described above.

Data Source Federation

Data sources, in the form of sensors, RFID tags, and other “smart items” are becoming more prevalent in today’s environment. Sensors and tags can be used to track objects and provide real-time information. Federated devices can provide new opportunities to access these nearly invisible information sources by federating them with other devices (such as PDAs or laptop computers) that can display their state, or even modify their behavior.

Federating with data sources can also be used in ubiquitous computing environments to provide support for context-aware applications. Knowing what data sources are currently in proximity to the user’s personal device can give a good sense of location, and data such as noise level, temperature, and other environmental factors can be used to modify the interaction. For example, if the noise level reported by nearby sensors is very high, a mobile device can make the decision to present information using the visual and haptic channels, rather than using audio.

Research projects that investigate software updates for embedded and networked devices point the way for data source federation. The OSGi Alliance is creating an open service delivery and management platform so that “software components can be installed, updated, or removed on the fly without having to disrupt the operation of the device.” Similarly, Sun Labs is researching “Small Programmable Object Technology,” or Sun SPOT®, which allows running Java programs to be moved between sensors. The flexibility inherent in these projects opens the possibility of federating devices to access data from nearby sensors or tags.

In data source federation, it is important to investigate the process of connecting and disconnecting devices. This topic of course also arises in input and output federation scenarios, but the sheer volume of sensors and tags available within a local area increases the magnitude of the problem.
If the system requires users to search for nearby devices and explicitly grant pairing rights, selecting a few sensors (or a nearby display) from a list of thousands of possible devices becomes overwhelming. On the other hand, totally automatic pairing with thousands of nearby devices will generally be undesirable, as the user is unlikely to want to interact with all of them and may be uncomfortable not knowing which devices are connecting at any given time.

**SOCIAL IMPACT OF VOICE TECHNOLOGIES**

A discussion of multimodality would be incomplete without paying some consideration to the social impact of voice technologies. As mentioned earlier in the chapter, speech is one of the most common input technologies after keyboards and pointing devices. However, communicating with computer devices using speech raises many issues regarding how people respond to technologies that engage in this very “human” activity. The “Media Equation,” as it was coined by Reeves & Nass, can be summarized by the idea that people treat interactions with computers and other media the same way that they treat interactions in real life (Reeves & Nass, 1996). Among other things, users react to and expect the same social phenomena in human-computer communication as in human-human communication, including following the rules of politeness and interpersonal difference. Nass & Braves (2005) extend these findings to state that humans are “Wired for Speech,” and have even stronger expectations about how systems that can speak or listen should behave.

In this section, we will reflect on one fundamental issue related to multimodal interactions that is implied by this work: the mismatch of modalities between input and output (James, 1998). When a device (or desktop application, for that matter) provides voice output, but does not allow voice input, this puts the user in a subordinate position to the computer, and may make the user feel out of control. As Brenda Laurel puts it:

“We...tend to expect symmetry between the input and output modalities of a system; that is, we expect that they are operating in the same sensory universe as the rest of the representation. If a computer talks to us, we want to be able to talk back, and vice versa.... In most systems, our side of the I/O equation is severely impoverished. The system can present images, sounds, movements, words, and possibly even speech, but we must act inside a straitjacket of menu items and mouse clicks. No wonder we often feel that computers are always in control—the system is holding all the cards! Working toward symmetry in input and output channels in human-computer activities can vastly improve our experience of engagement and agency.” (Laurel, 1993)

Control is not the only issue. Mismatching modality can also be perceived as impoliteness. The polite response to a letter is another letter; answering a letter with a phone call is less polite. Computer systems that require an input in a different modality than the modality used for output, according to Reeves & Nass (1996), force the user to make an impolite response.

Due to the factors discussed above, care should be taken when adding a modality to make sure that it is available both for input and output, if it is technically possible to do so. There is, however, every possibility that new generations of computer users who have been exposed to interfaces with modality mismatches since birth may not have the same control and politeness responses [changes in politeness behavior related to technology use have been shown to some extent in relation to mobile phones, for example (Ling, 2004)]. Although computer interfaces evolve at a much faster pace than humans, people who grow up using multimodal interfaces that may not conform to human-human social interaction standards may adapt their reactions to the computers and be more accepting of seemingly impolite behavior.
SUMMARY

This chapter has described some of the basic principles of multimodality. We began with a description of some of the ways that the human senses can be used to interact with a computer, and discussed the idea that modalities can be used redundantly, where more than one modality is used to either present or gather the same information, or complementarily, where information from more than one modality must be combined to produce the whole input or output message. Each of these methods can be used for either desktop or mobile interactions, although generally for different reasons.

Multimodal interfaces to desktop computers strive to provide natural mappings between the information to be input or output and the modality used. This more frequently leads to interfaces that use complementary modalities, or multimodal fusion. Desktop applications also use multimodality to support users with disabilities or to provide more usable security. Another interesting research area for multimodality is around the use of redundant output modalities to support users who move from desktop to mobile computers during the course of an interaction.

Mobile applications use multimodality to improve the input and output capabilities of the devices. Because mobile devices must be small to be portable, they often have very small visual displays and keypads. Voice and audio are obvious choices here, and have been used widely. Finally, because mobile devices are often used in contexts where the user is carrying out another (more primary) task, such as walking or driving, it is important to design interfaces that do not require too much of the user’s attention or overload any of the senses.

Next, we described an emerging area of human-computer interaction that seeks to combine the portability of mobile devices with the interaction capabilities of larger ambient devices, called device federation. Input and output federation can, and have already begun to, be used to support mobile users with both business and consumer applications. Federation with data sources, such as sensors and RFID tags, could also benefit business users and support context-awareness.

The final section of this chapter discussed an important consideration when using voice interactions, namely, the social implications. Based on continuing research from sociology, it is clear that people treat media in many of the same ways that they treat other people, and have many of the same expectations. This is especially true for voice-based systems, so care must be taken when using voice input and output.

FUTURE RESEARCH DIRECTIONS

The importance of multimodal interaction design will continue to increase as users move more and more towards interaction with mobile devices, and away from traditional desktop computing environments. Increasing wireless connectivity is shifting users toward an “always-on, always-available” mentality that will be supported by newer and better mobile devices.

The widespread use of mobile devices will require a focus on supporting work that is done within the context of other activities. This work has already begun to some extent, but there are open questions around the types of tasks users choose to engage in while busy doing other things and how to manage interruptions within an interaction. For example, in the vehicle context, it will be important to understand what kinds of tasks are of interest to users, and then create interfaces that will help users complete them safely and without creating an undue mental burden. Even without considering interruptions, it will be important to investigate the confirmation of actions taken by users whose attention is divided between interaction with a mobile device and interaction with the rest of the world.
The federated device concept discussed in this chapter certainly falls under the area of future research. Initial projects have shown that it should be possible to (wirelessly and seamlessly) interconnect mobile and ambient devices; what remains to be seen is how the interactions with device federations should be structured. What information should be shown on a personal display, as opposed to a public display? Should the personal device be used for input to a device federation, and if so, how should it operate? Will the personal device act as a remote control, or will users respond to it simply as one component of the larger system? These and other questions are important to understand as the world moves toward ubiquitous computing environments.

Finally, this chapter listed a wide range of modalities available for human-computer interactions. Some of these modalities are already part of many computer systems, such as voice and audio, while others are less widely used. Haptics and other modalities could be valuable additions to new interaction designs, but more research is required to understand where they would be most appropriate for everyday use.

INTRODUCTION

In 801, Harun Rashid offered Charlemagne a water clock, the like of which was inexistent in all of Europe at that time; the King’s court thought that a little devil was hidden inside the clock. In the 1930s, King Abdulaziz of Saudi Arabia had to convince his people that the radio was not the making of the devil and that it could in fact be used to broadcast and spread the Quran. In 2003, the Arab region is found to be still lagging in modern technologies adoption (UNDP, 2003). Thus, in a little more than 11 centuries, the Arabs were transformed from leaders to adopters, then to late adopters as far as technologies are concerned.

The Arab world is taken to mean the 22 members of the Arab League, accounting for more than 300 million people with an economy of 700 billion dollars. Although most Arabs practice Islam, they represent less than one third of all Muslims. The Arab world is often thought of as economically prosperous due to its oil resources; yet its total GDP is lower than that of Spain (UNDP, 2003).

Arab countries share language and culture but differ in size, geography, demographics, government type, etc. In terms of spending in and use of IT, statistics portray the Arab world as far from being up-to-date (UNDP, 2003).

This article raises the question of whether existing research models are appropriate to explain this delay. If certain characteristics proper to the Arab culture play an important role in explaining the delay in IT adoption, then we anticipate the answer to be that no existing model is able to adequately study the IT adoption phenomena in the Arab world.

THE ARAB WORLD AND IT

It is a recognized fact that the Arab world lags behind in terms of IT (Aberdeen, 2001; UNDP, 2003). (See Figure 1.) In 2001, Ajeeb reported that the number of Arab Web sites reached 1.24% of the Arab population (Ajeeb, 2001), it predicted that the number of Internet users would equal 5 million by 2001, and reiterated DITnet’s March
2000 prediction that Internet users would number ten to twelve million by the end of 2002. In fact, there were a reported 8.2 million users by the end of 2002.

To date, no Arab country has been able to develop its electronic commerce capabilities to the extent seen in the West.

**REASONS FOR THE LAG**

The lag can partly be explained by the delay with which technologies have traditionally reached Arab countries. Davison et al. (2000) suggested several other reasons: a perceived incompatibility between local cultures and imported technologies, a preference for autonomy and independence with respect to technology, and a lack of economic resources to acquire technology.

The first two of are plausible as is it often the case that IT stumbling blocks occur not because of technical reasons but rather because of human and social obstructions. The third reason can be excluded for the six Gulf countries which claim per capita revenues of nearly five times the average of the rest of the Arab countries. The rate of adoption of the Internet for these countries is up to fifteen times that of the rest of the Arab world.

Other factors also explain the low rate of Internet penetration in Arab nations as compared to the rest of the world. In these nations, the rate of penetration is essentially measured based on only one part of society: men.

**The Arab Woman**

Two thirds of the 65 million illiterate Arabs are women. Women make up only 4% of all Arab Internet users while in Europe women make up 42% on average. The UNDP states that the condition of women is one of the three main factors explaining the current state of economic development in the Arab world.

In that more than 40% of women in Arab countries are denied participation to the technological revolution, Arab nations are failing to integrate a considerable part of their human resources in their future economies.

**Information and IT**

When Arab countries invest in IT, they do so mainly in hardware. While this may be a characteristic of developing countries, it may also be viewed as Arabs’ distrust of anything immaterial. Software on the other hand is associated with innovation, creativity, and the free flow of information and knowledge, qualities that the Arabs have been found lacking (UNDP, 2003). Thus, not only Arabs are increasing their dependence to the West being consumers of hardware, they seem to be passive users of the software and intelligence produced elsewhere.

This issue leads to the tight relationship between information (and not IT, let alone hardware) and democracy and freedom. If Arab countries are truly “information shy” (Henry, 1998), then what information is to be shared and circulated by IT? Therefore, the Arab does not see what use he could make of IT and would therefore not consider it an instrument of development.
Figure 2a. While hardware is projected to represent less than 35% of all IT investments in the world...

Figure 2b. ...it will continue to represent more than 70% of all IT investments in the MENA region (Source: Aberdeen, 2001).

Culture

Culture is “[the] collective programming of the mind that distinguishes the members of one group of people from those of another” (Hofstede, 1991). For Ibn Khaldun, 14th century Arab sociologist, man is son to his habits and his environment, not to his nature and his moods.

Hill et al. (1998) claim that the Arab culture is one of the most complex of the world. It is complex for several reasons. Though the majority of Arabs are Muslim, many are Jewish or Christian while others are agnostic and even atheists. Many actions and symbols assume a particular significance. Often in traditional Arab cultures a handshake or the spoken word are seen as more legally binding than a signed contract and the written word has less significance than in other cultures.

For Arabs bartering is very different from what the West calls negotiating. The numerous steps involved in bartering hold social meanings, the least of which is to learn about and get more acquainted with the other so as to build trust in terms of the product quality. Selling and buying are social acts not replicated by technology.

In his study of Qatari and Emirati cultures, Solberg (2002) found that “wasta” (social connections and string-pulling) could be used to lower the level of uncertainty during business transactions. Even when more direct means are available, Arabs prefer wasta because of the human contact it offers. Wasta is a way of life that builds upon human interactions, a major part of an Arab’s life, which she or he may not be willing to sacrifice to technology.

Arabs tend to be more talkative than Westerners; they are fond of sentences with several adjectives, the number of which, combined with the length of sentences and the tone of the voice, make up an integral part of the message. For example, when a guest is offered a cookie, it is customary to not accept too keenly or quickly. It is up to the host to insist (invoking God) to convert the initial refusal into a yes. Arabs rarely say yes or no, rather, they are inclined to answer using less committed terms such as “usually” and “Inshallah”. The design of computer interfaces with only the “yes”, “no” and “cancel” options is clearly rooted in other cultural norms.

Theories and Research Models

Many research models are available to study IT adoption. Flowers et al. (1975), for example, built
upon the framework of Graves (1970) in which people would evolve through levels of “psychological existence” reflecting their personal values and lifestyles, which vary with their cultural programming.

Research using this framework suggests that dominant value systems of Middle-Eastern managers are conformist, sociocentric and existential and their dominant decision-making style is consultative (Amirshahi, 1997).

Another important stream is represented by Hofstede’s work (1991) which considers culture a national trait. The results of Hofstede’s research is a typology of cultures based on five cultural dimensions: power distance, individualism, masculinity, uncertainty avoidance, and long-term orientation.

In research pertaining to IT, some dimensions have been invoked more than others: individualism (Jarvenpaa et al., 1999), power distance (Simon, 2001) and masculinity (Hofstede, 2001b). Findings from Hofstede (2001b) show a relationship between masculinity and fax machines, and femininity and cellular phones. Like authority, a masculine trait, a fax is not interactive; and like exchange and dialogue, which are feminine traits, a cellular phone is interactive.

Certain Arab values could be mapped onto Hofstede’s cultural dimensions. What one calls “maslaha al amma” (public interest) happens to mean the exact opposite of individualism. In the Arab culture, public interest could even be extended to the notion of Umma (nation). Family commitments and responsibility towards authority figures and political leaders are often held as priorities over other matters. Arabs from the Gulf swear allegiance to the family, clan, tribe, religion, and nation (Abbas, 1987). Usunier (1993) suggests that Arab cultures tend to resemble cultures that are focused on the present and for whom the future (destiny) is inevitably predestined (Mektoub) by God (Inshallah: God willing). For Patai (1973), fatalism is a predominant trait of the Arab culture. If past-oriented cultures are more passive than future-oriented cultures, the Arabs should have an attitude that can be summarized as “if it is written then it will happen” henceforth they will not feel the urge to go toward the technology and will expect it to come to them.

LIMITATIONS OF EXISTING MODELS

The Absence of Arab Dimensions

If in Hofstede’s model, the first four dimensions are applicable to other cultures, it would be useful to more closely study Arab values in order to include them in existing models.

Cultures are likely to diverge rather than come together as we would assume on the basis of globalization and the democratization of media. Hofstede (2001b) has shown that cultures are diverging rather than converging. More specifically, current world events do not lend support to the hypothesis that Arab and Western cultures are closing in.

Current research models would therefore benefit from including Arab dimensions; otherwise they would risk being applicable only to those cultures for which they were developed or for the Arab culture to continue being perceived through the lens of another culture. This could be done following the example of the Far East cultures. These cultures were really only taken into account into Hofstede’s model with the addition of the fifth dimension, Confucian dynamism, thereafter called long-term orientation. It was added in order to complete Hofstede’s model since it was the dimension that distinguished western and far-eastern cultures.

The Implicit Cultural Homogeneity

Differences exist among Arab countries (Solberg, 2002), and even between different regions of a same country. This is even more noticeable as
the borders between Arab countries were often drawn arbitrarily during colonization.

Fundamental cultural differences exist between Sunnis and Shiites, among them masculinity (Noland, 2003). Sunnis are considered more “triumphant” (sic) while Shiites focus more on suffering. The two strains of Islam could therefore be considered at the extremes of the masculinity dimension although scores for this dimension place the Arab world at the midpoint of the scale. However, even Sunnis bear certain feminine traits such as seeking good relationships with leaders and cooperating with colleagues in order to foster equally good relationships with them (Weir, 2001).

Differences can also be found between the cultures of the Gulf and other nations of the Arab world. The discovery of oil in the 1930s resulted in an odd mix of traditional and tribal cultures with modern cultures. This mix did not manifest itself in North Africa resulting in the Arab world composed of countries generally having either people or oil\(^{10}\). Furthermore, North African countries have not always had Arab identity. Unlike the Gulf countries, they became Arabs at the same time as Muslims.

**The Cultural Barrier**

Arabs, Arab culture, and Arab religion have always been a black box for the Westerner. For instance, some westerners have a near-Manichean tendency to dichotomize (Good vs. Evil, Them vs. Us, etc.) and are fond of clash-of-civilizations theories (see Huntington, 1996). El-Solh and Mabro (1994, p. 14) show how the application of over-simplistic dichotomies to the study of gender relations in the Middle East have left out much of the flexibility women might have in actual terms. The simple idea that the sexes have a complementary role in Arab society has often been misunderstood in Western studies as a binary opposition with a tacit hierarchy.

Furthermore, if by fatalism it is understood that humans have no say in their destiny, then the concept of time orientation of Patai (1973) originates from a fundamentally inaccurate understanding of a large part of the Arab world. Islam is founded on the promise of salvation (Jenna) or the threat of damnation (Jehenna). Debates on the “kadha and kadar”\(^{11}\) (destiny and predestination) continue to fuel the controversy that divides theologians on the issue. Suffice it to mention that Arab societies do not necessarily neatly fit within cultures anchored in either the past or the present.

**CONCLUSION**

Significant contradictions may exist between how Arabs perceive themselves and how they are perceived by others. For example, Hill et al. (1998) argue that the adoption of technologies is rarely in quest of imitating the West. But Ibn Khaldun maintains that imitation is characteristic of Arabs. Abbas and Al-Shakti, (1985) even suggested that Arab executives are the product of cultural values that tend to produce more followers than leaders. Yet, imitation is sometimes suspicious in the Muslim’s eye as some believe that imitation of the non-Muslims is “haram” (sinful) While it is also believed that imitating non-Muslims is permissible, the average Arab Muslim sometimes wonders when imitation stops being haram and starts being hallal (allowed)\(^{12}\). How to reconcile these points of view?

Two theories seem promising in that they may complement the research models we reviewed here. Social Identity Theory recognizes that cultural layers exist that describe different levels of programming (social, national, regional, religious, contextual, organizational, etc.).

Abdul-Gader and Kozar (1995) borrowed the construct of technological alienation from psychosociology to explain certain purchase and use decisions of IT. They showed that alienated
individuals resist any kind of technology adoption. More generally, Value-Expectancy Theory (Feather, 1995) promises to enrich the debate on IT adoption by Arabs since it addresses the issue of the value attributed to things by individuals and their expectations, founded or not, such as their resistance to the possible danger of technological and cultural dependence. This is all the more valid that Arabs view IT as a technology, not as a medium of knowledge and of accessing knowledge, something they need direly as evidenced by the conclusions of the UNDP (2003).

REFERENCES

**KEY TERMS**

**Arab World:** The Arab world is taken to include all 22 countries members of the Arab League.

**Culture:** According to Hofstede (1991), it is “[the] collective programming of the mind that distinguishes the members of one group of people from those of another”. For the 14th century Arab scholar, Ibn Khaldun, man is son to his habits and his environment, not to his nature and his moods. In all the literature about culture, there is a common understanding that culture is an abstraction from concrete behaviour but is not behaviour itself. Hofstede’s typology includes five cultural dimensions:

- **Individualism:** as opposed to collectivism, describes the degree to which a culture relies on and has allegiance to the self or the group.
- **Power Distance:** reflects the degree to which a culture believes how institutional and organizational power should be distributed.
- **Masculinity:** indicates the degree to which a culture values such behaviours as assertiveness, achievement, acquisition of wealth, social supports and the quality of life.
- **Uncertainty Avoidance:** refers to the extent to which a culture feels threatened by
ambiguous, uncertain situations and tries to avoid them.

- Long-Term Orientation: reflects the degree to which a culture is oriented toward the search for virtuous behaviour rather than being oriented towards the search for truth.

Information Technology: Hardware, software, network and services related to the use and operation of equipment with the aim of processing and communication of analogue and digital data, information, and knowledge. These include computers and computer applications such as the Internet, Intranets, Extranets, Electronic Data Interchange, electronic commerce, mobile and fixed lines, etc.

ENDNOTES

1 Most technological innovations are adopted by the Arabs with some delay. For example, if the printing press was invented around 1450, the first Arab book to have been printed was the Quran, in 1537 in Venice. Arabic character-based printing reached the Arabs only in 1728 under the reign of Ahmed III (1703-1730) when the Arabs were occupied by the Ottoman Empire. Bukhara (today’s Uzbekistan) delayed the introduction of printing until 1917 (See Khalid, 1994). It is as though in the Muslim world, the advent of printing broke the ulama’s long-established control of knowledge. Similarly to the Bible and the printing press, no longer could knowledge be obtained through someone “more knowledgeable”. It could be read and understood - or misunderstood—in libraries, schools, and even homes. Later, while e-mail was invented in 1971, the first Arabic Web-based mail solution was released in December 1998 (see http://web1.maktoob.com/maktoob/press1998/press1998-1.html). See more on Kaitlin Duck Sherwood’s site, http://www.webfoot.com/advice/WrittenArabic.html.

4 For Muslim Arabs, this may be explained historically and religiously by the fact that when the Divine message was delivered, the Angel Gabriel dictated the Quranic verses to the Prophet Muhammad. In all pre-modern times, documents were not copied; they were memorized, where there was no other way to preserve them.

In his book, “The Saddam Years” (Fayard, 2003), Saman Abdul Majid, personal interpreter to the deposed dictator, explains how, in 1993, President Clinton sent a secret agent to Iraq to suggest that a new leaf be turned over and that discussions be resumed. Saddam did not immediately answer, an act that Clinton took as a refusal. That file was then closed. In fact, Saddam was expecting a more solid and thought-out proposition to be put forward, and was surprised that Clinton did not come through with one. This miscommunication between two men of very different cultures has had the now all-too known consequences.

6 It is assumed that most readers are familiar with Hofstede’s work. Due to space limitations, details of his work will not be elaborated here. For more information, the reader is referred to Hofstede (2001b).

7 Also of interest is the GLOBE (Global Leader and Organizational Behavior Effectiveness) project which seeks to determine the relationship between leadership and societal culture (House et al., 2002). GLOBE uses
nine dimensions, six of which are the same as Hofstede’s: uncertainty avoidance, power distance, institutional collectivism, in-group collectivism, gender egalitarianism, assertiveness, future orientation, performance orientation, and humane orientation. Using these dimensions, Gupta et al. (2002) identified 10 “cultural clusters”: Asia, Anglo, Arab, Germanic Europe, Latin Europe, Eastern Europe, Confucian Asia, Latin America, Sub-Saharan Africa and Nordic Europe. Unfortunately, often in GLOBE papers, the Arab cluster is composed of very few countries (see Abdalla and Al-Homoud, 2001). Other countries, such as Turkey, have disconcertingly been found in such “Arab clusters” (see Kabasakal & Bodur, 2002) ignoring the fact that Turkey is not a member of the Arab League and overlooking its claim to European Union membership. Perhaps even in this order, especially if one takes into account the famous proverb in which an Arab states: “Me, against my brother; my brother and I against our cousin; my brother, my cousin and I against all others.” Was it not written of Ishmael (and by extension of all Arab children) in the Bible that “And he will be a wild man; his hand will be against every man, and every man’s hand against him; and he shall dwell in the presence of all his brethren” (Genesis 16:12). This, however, does not seem to hold any longer given the events that took place between Iraq and Kuwait in 1990-1991 as well as since then. Judging by the lack of cultural sensitivity of today’s’ graphical user interfaces and icons, that technology is all but coming to the Arab culture. The only exception being Iraq. This highly philosophical issue revolves around the overly simplified question that if God had already decided on much of what we humans will do on Earth even before we were created, what is the Last Judgment about?

One has to remember that the digging of the trenches around Madina in the battle of Al-Ahzab, which was led by the prophet Mohamed (Peace Be Upon Him) and his companions as a defense system, and the application of Omar Ibn Al-Khattab, the second khalif after the prophet, of the filing system in the Islamic State, for organizing taxes on cultivated land and payroll of the soldiers are examples of imitation as they were borrowed from Non-Muslim Persians (see more on this subject on www.islam1.org/khutub/Imitation_of_None-Muslims.htm, accessed April 13, 2004).
Chapter 1.11

Information Technology Acceptance across Cultures

Amel Ben Zakour
FSJEGJ, Tunisia

ABSTRACT

This chapter introduces national culture as a possible factor accounting for the differences in information technology adoption and use between countries. Based upon culture theory and the technology acceptance model (TAM), the author offers a conceptual model aiming at better understanding IT acceptance across countries of different cultures. It has been argued that six value dimensions—individualism/collectivism, power distance, uncertainty avoidance, masculinity/femininity, high/low context, and polychronism/monochronism—act as moderators of the TAM relationships. Furthermore, the author aims at helping IT designers and IT managers all over the world to understand why certain national cultural values may be congruent or not with the IT to be designed or implemented.

INTRODUCTION

With the globalization context, companies all over the world (developed and less developed ones) are using information technologies (IT) that have become more and more sophisticated and complex. These technologies provide huge opportunities to gain a competitive advantage since information could be obtained, processed and transmitted at very low costs (Porter & Millar, 1985). Nevertheless, in order for companies to take full advantage of IT, they have to understand the new challenge provided by these IT (Tapscott & Caston, 1994). Actually, even though organizations adopt IT that best fit their business activities, they cannot guarantee performance leveraging unless the organization members appropriately use it. According to Agarwal (1999), “Acquiring appropriate IT is necessary but not sufficient condition for utilizing it effectively” (p. 85). With the globalization incurring unlimited interconnection possibilities and an increasing number of partnerships, firms belonging to less-developed countries are investing massively in new infor-
Information Technology Acceptance across Cultures

Information technologies that are expected to improve their competitiveness. Nevertheless, we notice that although these technologies are voluntarily purchased by organizations, they are not fully used or accepted in the work context at the individual level. Differences in IT usage and adoption are reported in many descriptive studies pertaining to IT implementation in different countries and contexts (Danowitz, Nassef, & Goodman, 1995; Goodman & Green, 1992). The main causes of these differences that have been identified are technical, economic, or managerial.

Our main concern in this chapter is to shed light on an issue that deserves a closer study which is the cultural factor. Indeed, the latter is expected to be an interesting explanation for the differences in IT adoption and use between countries. Furthermore, culture has been used as an explanatory factor of several managerial and organizational issues (Fisher & Smith, 2003; Thomas & Pekerti, 2003; Laurent, 1983; Hofstede, 1985; Silvester, 1990; Hernandez, 2000). The literature in the information systems (IS) field provides few studies attempting to explore the nature of the relationship between culture and IT implementation. Furthermore, most of the prior cross-cultural studies on IS hardly have focused on the individual behavior toward IT; they generally have focused on IT transfer (Hill, Loch, Straub, & El-Sheshai, 1998), on organizational characteristics related to IT implementation (Robey & Rodriguez-Diaz, 1989), or on end-user computing characteristics (Igbaria & Zviran, 1996). Moreover, these studies have focused on the concept of culture at the macro level of analysis (i.e., they attempted to compare IS-related behaviors in different countries, supposing that each country is characterized by a different set of cultural values). For example, when studying IT diffusion in Japan and the USA, Straub (1994), using Hofstede’s cultural classification of 51 countries and three regions, supposed that the Japanese are high in uncertainty avoidance (ranked 7th) and the Americans are low in this dimension (ranked 43rd). Even though there is accumulated evidence pointing to national culture as a factor influencing IT adoption and acceptance, few studies have handled this issue at the individual level. Therefore, the main objective of this chapter is to provide a conceptual framework that examines the influence of national culture, though a macro-level construct, on IT adoption by integrating specific cultural value dimensions to technology acceptance model (TAM) (Davis, Bagozzi, & Warshaw, 1989). This framework is aimed at being used at the individual level since cultural dimensions characterizing national culture (i.e., individualism/collectivism, power distance, masculinity/femininity, uncertainty avoidance, high/low context of communication and polychronism/monochronism) are value dimensions considered as individual psychological dispositions and TAM is designed to capture acceptance at the individual level.

We have divided the chapter into four parts. The first part is devoted to a review of comparative and international studies in the IS field. The second part presents an overview on culture theory, which is found in the literature of various disciplines such as anthropology or cross-cultural psychology. The third part focuses on the presentation of TAM (Davis et al., 1989), judged to be the most parsimonious model of information technology usage, as well as TAM-relevant extensions. The fourth part is aimed at presenting the rationale sustaining the conceptual framework developed to explain how national culture could influence IT usage.

STUDIES INVOLVING NATIONAL CULTURE AND INFORMATION SYSTEMS

Prior researches focusing on cultural issues in the IS field were conducted mainly through two main and different perspectives. According to Ronen and Shenkar (1988), the *emic* perspective “studies
behavior from within a single culture-system” (p. 72), whereas the etic perspective focuses on universals and studies behavior “from a position outside the system and in comparison with various cultures” (p. 72). Early and Singh (1995) have provided more comprehensive classifications of international and intercultural studies. Early and Singh (1995) have proposed four research approaches to study these issues; namely, unitary form, gestalt form, reduced form, and hybrid form. The difference between these approaches stems from “examining whole systems rather than their components” (Early & Singh, 1995, p. 330).

The unitary form emphasizes the understanding of a particular cultural group using the specific constructs and concepts of this group. Actually, this kind of approach is not so much interested in cultural dimensions per se as much as it focuses on knowing how a certain behavior is manifested in a particular setting. There is no attempt to establish universals based upon such a perspective.

The gestalt form, unlike the unitary system form, focuses on the comparison of the phenomenon with a similar one in different contexts, and “constructs and relationships are derived from general principles rather than from the systems themselves” (Early & Singh, 1995, p. 330). This approach is appropriate when the researcher is concerned with the generalizability of a model across nations.

The reduced form examines the phenomenon of interest with regard to a specific feature of culture, such as the case dealing with one cultural dimension when hypothesizing about a certain behavior. Generally, comparative studies that explain the differences in the applicability of a model by the country of origin actually are using the reduced form. The cultural explanation is provided ad hoc.

The hybrid form goes beyond comparison in search of similarities and differences, and it allows researchers to explain how certain aspects of a culture can explain the phenomenon. “The reliance on nation or culture as a ‘black box’ is abandoned in favor of a more precise specification of theoretical relationships” (Early & Singh, 1995, p. 334).

In order to have a better visibility of cross-cultural researches in the IS field, we present in Table 1 a summary of cross-cultural studies on IS, grouped according to Early and Singh’s classification.

Our current research follows more the hybrid form since we integrate to TAM a set of universal cultural dimensions deemed to characterize national culture.

CULTURE THEORY

Even though originally rooted in anthropology, a population-level discipline, culture has been defined and researched by many other disciplines such as cross-cultural psychology. Culture has been defined according to several perspectives. Definitions go from the most complex and the most comprehensive (Kluckhohn, 1962) to the simplest (Hofstede, 1997; Triandis, 1972). According to Kluckhohn (1962), “Culture consists of patterns, explicit and implicit, of and for behavior acquired and transmitted by symbols, constituting the distinctive achievement of human groups, including their embodiments in artifacts; the essential core of culture consists of traditional (i.e., historically derived and selected) ideas and especially their attached values; culture systems may, in one hand, be considered as product of action, on the other hand, as conditioning influences upon further action” (p. 73). Hofstede (1997) defines culture as “the collective programming of the mind which distinguishes the members of one group or category of people from another” (p. 5).

Researchers in comparative and intercultural management most of the time use the concept of organizational culture or national culture. Nevertheless, they omit the fact that individual behaviors and attitudes in an organizational context could be influenced by other kinds of cultures. Indeed, culture is a multi-level phenomenon that could be approached according to different levels such as region, ethnic group, religion, language, nation, profession, firm, gender, social class (Hofstede, 1997; Karahanna, Evaristo, & Srite, 2005; Schneider & Barsoux, 2003). Culture also could be defined according to continental or political belonging (Lévi-Strauss, 1985). Furthermore, these different cultures interact with each other. For example, several ethnic groups are found in India.

In the present study, we are interested in national culture since it has been shown to influence management and organizations (Hernandez, 2000; Hofstede, 1985; Laurent, 1983; Silvester, 1990; Zghal, 1994). In a comparative study involving the USA, Indonesia, Japan, and nine countries from Western Europe, Laurent (1983) has found that managers from these countries have different behavioral patterns. For example, the Americans believe that the main goal of a hierarchical structure is to organize tasks and facilitate problem resolution, whereas for the Japanese, the Indonesians, or the Italians, the goal is to highlight the authority structure. In the same vein, Hofstede (1985) has demonstrated that the employees’ perceptions of the organization and its management depend on the intensity of two national values: power distance and uncertainty avoidance. Four implicit patterns of organization conception are defined: (1) the pyramid pattern (both power distance and uncertainty avoidance) are high, which corresponds to the hierarchical bureaucracy, quite common in France and the Mediterranean countries; (2) the well-oiled machine pattern (low power distance and high uncertainty avoidance), which corresponds to an impersonal bureaucracy found, for example, in Germany; (3) the village market pattern (both power distance and uncertainty avoidance are low), which is found in Great Britain and Nordic countries; and (4) the family pattern (high power distance and low uncertainty avoidance), which is found for example in African and Asian countries. Hernandez (2000) also has shown that African management systems are influenced by a national cultural trait: paternalism. The latter corresponds to high power distance and relationships based upon mutual trust. Paternalism also has been found to be perceived positively in Tunisian culture contrarily to American culture, which is focused on contractual relationships or Dutch culture, which is focused on consensual relationships (D’Iribarne, 1989). In a comparative study between France and Germany, Silvester (1990) has confirmed the results obtained by Hofstede (1985), showing that the French organization could be assimilated to a pyramid and the German one.
Information Technology Acceptance across Cultures

to a well-oiled machine. For example, they found that French managers have a prescriptive kind of work, whereas German managers have cooperative kind of work through which employees could learn and build a collective identity.

Several sets of dimensions have been developed to characterize the concept of national culture. Table 2 provides an overview of the most known cultural dimensions found in several fields of studies.

The analysis of the culture frameworks in Table 2 reveals an overlap of cultural dimensions identified by the various authors. Even though the definitions of these dimensions are not fully convergent in all the cases, still they show some similarities. Table 3 gives an overview of the similarities that exist between these dimensions. The current research will use the following dimensions: individualism/collectivism, masculinity/femininity, uncertainty avoidance, power distance (Hofstede, 1997), high context/low context (Hall, 1989), and time perception (Hall, 1989; Trompenaars & Hampden-Turner, 1998).

Several reasons lead us to investigate national culture through these six dimensions.

First, these dimensions rely on variables that are linked more directly to social and organizational process: they focus on human values rather

than on general beliefs about the way we see the world. Indeed, “culture is primarily a manifestation of core values” (Straub, Loch, Evaristo, Karahanna, & Srite, 2002); therefore, in order to better capture the relationship between culture and behavior, Triandis suggests using values (Triandis, 1972). Second, the first four dimensions (Hofstede’s cultural dimensions) constitute the most used and most recognized dimensions as a whole or separately in studying cross-cultural issues in management and organizations. Because of its global coverage in terms of respondents, it seems that Hofstede’s study has been unrivaled (Smith & Bond, 1999). In fact, the identification of the cultural dimensions was based upon a field study covering a sample of 40 countries in which more than 116,000 questionnaires were collected. Hofstede’s work also has been validated directly or indirectly by many other researchers in different settings (The Chinese Culture Connection, 1987; Hofstede & Bond, 1984; Shackleton & Ali, 1990). The studies that have been conducted

Information Technology Acceptance across Cultures

since Hofstede’s work (The Chinese Culture Connection, 1987; Schwartz, 1994; Trompenaars & Hampden-Turner, 1998) exploring the national culture through values have sustained and amplified his findings rather than having contradicted them (Smith & Bond, 1999). The two dimensions related to time orientation and communication context are based upon Hall’s well-established studies on intercultural communications. Indeed, cross-cultural studies of styles of communication, briefly reviewed by Smith and Bond (1999), reveal a divergence between societies in several aspects of communication and provide evidence sustaining Hall’s contention about high/low context (Gudykunst & Ting-Toomey, 1988).

In the following paragraphs, we are going to give more explanations about the origins of these cultural dimensions.

**Power Distance (PDI)**

According to Hofstede (1997), individuals in high PDI societies accept the unequal distribution of power, which is what Schwartz (1994) calls hierarchy. The latter is linked to the inequality of the distribution of power, roles, and resources. Conversely, in low PDI societies, individuals do not accept this inequality. Indeed, in an organizational context, subordinates can criticize their superiors, and superiors are supposed to take into account this criticism, since everyone is free to express his or her disagreement about any issue.

In a low PDI organization, the hierarchical system depicts an inequality of roles that may change over time (Hofstede, 1997). This kind of behavior is not tolerable in a society that emphasizes authority. What Schwartz identifies as egalitarianism (also egalitarian commitment) (Schwartz, 1994) can be assimilated to the concept of low PDI advocated by Hofstede.

Egalitarianism dimension is driven by values expressing the transcendence of selfish interests and leading to a voluntary commitment to promote welfare of other individuals (e.g., social justice or loyalty). Even though Schwartz explains the opposition hierarchy/egalitarianism by psychological concepts (i.e., self-enhancement/self-transcendence), Hofstede explains PDI dimension, relying more on social contexts in which individuals have learned to accept or reject the inequality of relationships between people (such as country history, ideologies, language). These two dimensions are fairly comparable and valid to characterize national culture.

**Individualism/Collectivism (I/C)**

Individualism concept takes its roots in the Western world. Indeed, in Britain, the ideas of Hobbes and Adam Smith about the primacy of the self-interested individual sustain this concept. In contrast, Confucianism in the Eastern world, emphasizing virtue, loyalty, reciprocity in human relations, righteousness, and filial piety, underlies a collectivistic view of the world. Even though some societies are characterized as individualistic and others as collectivistic, they have to deal with both individualistic and collectivistic orientations. These orientations co-exist, and what makes the difference among societies is the extent to which they emphasize individualistic and collectivistic values.

Individualism/collectivism has been criticized by several disciplines and especially psychology (for a review, see Kagitçibasi, 1997). Nevertheless, it is still the focal dimension in cross-cultural studies and has been used most often as an explanatory variable (Schwartz, 1994).

Hui and Triandis (1986) define collectivism as “a cluster of attitudes, beliefs, and behaviors toward a wide variety of people” (p. 240). Seven aspects of collectivism has shown to be relevant in characterizing it, which is the consideration of the implications of our decisions for other people, the sharing of material resources, the sharing of nonmaterial resources (e.g., affection or fun), the susceptibility to social influence, self-presentation and facework, the sharing of outcomes and
the feeling of involvement in others’ lives (Hui & Triandis, 1986).

All the dimensions pertaining to this concept of I/C (Hofstede, 1980), developed by Schwartz (autonomy/conservatism), Trompenaars and Hampden-Turner (individualism/communitarianism) and Kluckhohn and Strodtbeck (relational orientation), deal with one unique issue: the person’s relationship to other people. Schwartz defines autonomy/conservatism according to the person’s embeddedness in the group; meanwhile, Hofstede, Trompenaars, and Hampden-Turner define I/C, emphasizing individual vs. group interest.

Two underlying ideas support the autonomy/conservatism dimension. The first idea explains the autonomy pole: an individual is considered autonomous when he or she is holding independent rights and desires and the relationship he or she has with the others is dictated by self-interest and negotiated agreements. The second idea explains the conservatism pole: an individual is part of a group and his or her significance pertains to his or her participation in and identification with the group (Schwartz, 1994). At the individual level, Schwartz argues that there are two kinds of values: individualistic values, which are hedonism, achievement, self-direction, social power, and stimulation; and collectivistic values, which are pro-social, restrictive conformity, security, and tradition.

According to Hofstede, in individualist cultures, “the interests of the individuals prevail over the interests of the group” (Hofstede, 1997, p. 50). People are supposed to decide and achieve alone. In collectivist cultures, people prefer to decide and act in a group so that responsibility and reward will be shared. “Collectivism is associated with childrearing patterns that emphasize conformity, obedience and reliability” (Triandis, 1989, p. 16).

Individualism/Collectivism construct is considered to be the most important aspect of cultural differences because of its parsimony and its potential to explain variations in economic development (Kagitçibasi, 1997). Indeed, according to Hofstede and Bond (1988), there is a high correlation between individualism and the level of economic growth at the national level.

**Masculinity/Femininity (MAS)**

The MAS dimension was derived empirically from Hofstede’s work on work-related values across countries. Hofstede distinguishes between cultures according to their emphasis on achievement or on interpersonal harmony. In labeling this dimension according to gender, Hofstede refers to the social and culturally determined roles associated with men vs. women and not to the biological distinction. Several other studies have identified almost the same dimension labeled as mastery/harmony (Schwartz, 1994) or achievement/ascription (Trompenaars & Hampden-Turner, 1998). All the dimensions show an obvious overlapping, since they are driven by almost the same set of opposing values. Empirically, a cross-cultural study conducted by Schwartz (1994) shows a positive correlation between MAS and mastery. In one pole, the underlying values are assertiveness, material success, control or mastery, and competition. This is the pole of masculinity (mastery, achievement). In the pole of femininity, the dominant values are modesty, caring for others, warm relationships, solidarity, and the quality of work life.

**Uncertainty Avoidance**

This dimension has been inferred from Hofstede’s survey pertaining to the theme of work stress when he addressed his questionnaire to IBM employees. According to Hofstede, the extent to which individuals tend to avoid uncertainty can differentiate among countries. Indeed, the feeling of uncertainty is something that could be acquired and learned in the diverse institutions of a society such as family, school, or state. Each society will have its proper behavioral model toward this
feeling of uncertainty. Hofstede argues that uncertainty is strongly linked to anxiety. The latter could be overcome through technology, laws, and religion (Hofstede, 1997). In strong uncertainty avoidance societies like South America, people have rule-oriented behaviors. On the contrary, in societies where uncertainty avoidance is weak, people do not need formal rules to adopt a specific behavior. In the same vein, Triandis (1989) makes the difference between loose and tight cultures. He sustains that loose cultures encourage freedom and deviation from norms, whereas in tight cultures, norms are promoted, and deviation from those norms is punished. Shuper, Sorrentino, Otsubo, Hodson, and Walker (2004) also have confirmed that countries do differ in uncertainty orientation. Indeed, they have found that Canada is an uncertainty-oriented society that copes with uncertainty by attaining clarity and finding out new information about the self and the environment, and Japan is a certainty-oriented society that copes with uncertainty by maintaining clarity and adhering to what is already known (Shuper et al., 2004).

**Time Orientation**

The most overlapping dimensions are attitudes to time (Trompenaars & Hampden-Turner, 1998), time perception (Hall, 1989), and time orientation (Kluckhohn & Strodtbeck, 1961), which highlight two main dimensions describing the concept of time: the structure of time (discrete vs. continuous) and the horizon of time reference (reference to the past, present, or future). According to Hall and Hall (1987), a monochronic person runs one activity at a time and associates to each activity a precise time, while a polychronic person can perform many activities simultaneously without preparing an exact schedule, or if it exists, it can be ignored. Studies conducted in this sense (Schramm-Nielsen, 2000) have shown that polychronic time is very specific to the Mediterranean countries, the Middle East, the Arab world, and Latin America. Indeed, in these countries, people assume that time is elastic, and thus, the appointment time and planning are not always respected. Actually, this behavior is considered very normal, because individuals emphasize interpersonal relationships. On the contrary, North-European and Anglo-Saxon countries usually adopt the monochronic time. In these countries, time is divided into segments and rigorously scheduled so that each activity will be assigned a specific and unique time within which it will be performed. Priorities also are classified according to time. Consequently, planning and schedules are sacred and cannot be changed. Trompenaars and Hampden-Turner (1998) called these two types of time systems the sequential and the synchronic. “Time can be legitimately conceived of as a line of sequential events passing us at regular intervals. It can also be conceived as cyclical and repetitive” (Trompenaars & Hampden-Turner, 1998, p. 126).

The time assumption underlying the remaining dimensions (long-term orientation, Confucian work dynamism, and conservatism) pertains to the temporal horizons to which persons refer in their activities: past, present, and future. Confucian work dynamism is based upon values derived from Confucian teachings. In one pole, called by Hofstede long-term orientation, are found values such as perseverance and thriftiness, and in the short-term orientation pole are found values such as personal steadiness and stability and respect for tradition.

Schwartz identifies a value called conservatism that is similar in many aspects to the Confucian work dynamism, since it emphasizes the cohesiveness of the group and the respect for the traditional order of the group. This emphasis is depicted in at least three values characterizing Confucian work dynamism: ordering relationships, personal steadiness, and respect for tradition.
High Context/Low Context of Communication

The nature of the communication context has been highlighted only by Hall (1989) as a relevant dimension capable of discriminating between cultures. In order to better understand the concept of high context/low context of communication, it is crucial to define context and to shed light on the relationship between meaning, context, and communication. According to Hall and Hall (1987), “context is the information that surrounds an event and inextricably bound up with the meaning of that event” (p. 7). A distinction can be made between internal and external contexting. The former depends on past experience internalized into a person or the structure of the nervous system or both (Hall, 1989). The latter is based on the situation and/or setting pertaining to a particular event. Meaning is the interpretation attributed to a particular message or communication. “Words and sentences have different meanings depending on the context in which they are embedded” (Hall, 1983, p. 56). According to Hall (1989), meaning is made up of the message and the two kinds of context, which are the background and preprogrammed responses of the recipient on the one hand and the situation on the other hand. Since information, context, and meaning are the key components in defining high and low context cultures, Hall contends that “the more information that is shared, … the higher the context” (Hall, 1983, p. 56). Therefore, high-context communications are those that rely more on context (shared or stored information) than on transmitted information. In this case, little of the meaning is conveyed in the transmitted part of the message. In high-context cultures, “simple messages with deep meaning flow freely” (Hall, 1989, p. 39). People do not need to elaborate their speech codes because of the largely shared assumptions about the rules of communication. Indeed, the emphasis is more on the manner of transmitting a message than on the message per se. For example, gestures and voice intonation can make the difference between messages of the same content. On the contrary, low-context communications rely more on the transmitted part of the message and less on the context. Americans, Germans, Swiss, and Scandinavians are found to be low-context. In such cultures, characterized by Hall (1989) as fragmented cultures, people have more elaborate codes in communication because of their lack of shared assumptions about communication rules. All the meaning they try to transmit is reflected in the information contained in the literal message. In this case, it seems obvious that there is no need to use different kinds of signals as a guide to interpretation.

TECHNOLOGY ACCEPTANCE MODEL

The technology acceptance model (TAM) is considered a tool designed to understand and measure the IT individual determinants of use. The most comprehensive TAM is designed by Davis et al. (1989). It is based on two key concepts: perceived usefulness (PU), defined as “the prospective user’s subjective probability that using a specific application system will increase his or her job performance within an organizational context” (p. 985); and perceived ease of use (PEOU), defined as “the degree to which the prospective user expects the target system to be free of effort” (p. 985). According to this model, an individual who intends to use a system will have two types of beliefs (PU and PEOU), which influence behavioral intention through attitudes. In addition, PU will have a direct effect on behavioral intention. Finally, external variables will have a direct effect on the two beliefs.

In order to study individual adoption of IT, the present research will be using the TAM. The use of the latter is motivated by theoretical, empirical, and practical considerations. From a theoretical point of view, TAM takes its roots
from the theory of reasoned action (TRA) (Ajzen & Fishbein, 1980). The latter provides a simple model to understand and predict a person’s behavior. It goes from the principle that an individual behaves most of the time in a rational manner, takes into account available information, and assesses consequences of his or her actions implicitly or explicitly (Ajzen, 1988). According to TRA, individual behavior is influenced by behavioral intentions. These intentions at the same time are determined by attitudes toward this behavior and subjective norms. In turn, attitudes and subjective norms are dependent on behavioral and normative beliefs, respectively.

TRA is one of the most prominent theories of social psychology and the most powerful to predict a specific behavior (Agarwal, 1999; Liska, 1984). Two meta-analyses of empirical studies testing the TRA conducted by Sheppard, Hartwick, and Warshaw (1988) show that the theory has a powerful predictive utility. Moreover, it is proved to be broadly applicable to a large array of behaviors (Agarwal, 1999; Sheppard et al., 1988). A study of a large variety of behaviors, such as voting for a presidential candidate, having an abortion, or smoking marijuana, confirms the causal relationships of the model, considering attitudes and subjective norms as independent variables and intention as the dependent variable (Ajzen, 1988).

From an empirical point of view, several researches applied TAM to different kinds of IT, such as text processing application (Davis et al., 1989), computers (Igbaria, 1995), e-mail (Karahanna & Straub, 1999), the World Wide Web (Moon & Kim, 2001), with different kinds of end user populations, such as students (Davis et al., 1989; Mathieson, 1991; Szajna, 1996), employees (Karahanna, Straub, & Chervany, 1999; Lucas & Spitler, 2000), or even physicians (Hu, Chau, Sheng, & Tam, 1999), and in different organizational contexts. Other studies test TAM and compare it to competing theories such as TRA (Davis et al., 1989) or Theory of Planned Behavior (Mathieson, 1991). All of these studies show that TAM has a strong predictive power. Moreover, TAM extensions (Agarwal & Karahanna, 2000; Agarwal & Prasad, 1999; Dishaw & Strong, 1999; Lucas & Spitler, 1999; Venkatesh & Davis, 2000; Venkatesh, Speir, & Morris, 2002), the main objective of which is to extend TAM by integrating other variables hypothesized to influence directly TAM constructs or indirectly by moderating the relationships among them, support its causal relationships and confirm its predictive utility. A nonexhaustive summary of TAM extensions is presented in Table 4.

From a practical point of view, TAM gives the possibility to practitioners, especially IS designers, to identify the areas in which we can act to improve IT use. Indeed, the two key concepts of TAM (i.e., perceived usefulness and perceived ease of use) could be controlled by IT designers. Consequently, developers could make it easy to use IT and to identify more concretely managerial benefits driven by IT that they are developing.

### THE INFLUENCE OF NATIONAL CULTURE ON IT ADOPTION: CONCEPTUAL MODEL AND RESEARCH PROPOSITIONS

We draw upon an extension of the TAM that integrates subjective norms (Venkatesh & Morris, 2000) as a determinant of the intention to use IT. Subjective norms reflect a person’s perception of the social pressure to perform the behavior in question. The importance attributed to social norms in determining and predicting behavior varies across cultures (Triandis, 1977); therefore, we expect that integrating subjective norms will strengthen our understanding of differences in behavioral intentions and will allow a better capturing of the cultural effect on IT use.

In order to explore the cultural factor, we rely upon Hofstede’s four cultural dimensions:

Information Technology Acceptance across Cultures

- **Individualism/collectivism:** Defined as the degree to which people in a society are integrated into strong cohesive ingroups.
- **Masculinity/femininity:** Defined as the extent to which a society attributes qualities such as assertiveness, material success to men, and modesty and concern about the quality of life to women.
- **Uncertainty avoidance:** Defined as the extent to which the members of a culture feel threatened by uncertain and unknown situations.
- **Power distance:** Defined as the extent to which the less powerful members of institutions and organization within a country expect and accept that power is distributed unequally.

Moreover, we rely upon Hall’s work on intercultural communication, which is based on two key cultural dimensions:

- **High context/low context:** Defined as the extent to which people are aware of and pay attention to all types of situational and contextual cues when interpreting messages.
- **Polychronism (vs. monochronism):** Defined as the preference to perform many activities at the same time.

These dimensions are hypothesized to have direct effects or moderator ones on TAM constructs and relationships. Integrating cultural dimensions to TAM is an attempt to better understand the genuine influence of national culture on IT adoption at the individual level. Indeed, cross-cultural studies on IS (see Table 1) focused on IS phenomena at the organizational level, such as IT transfer. Moreover, all the authors (except Srite & Karahanna, 2006) do not conceptualize national culture at the individual level. They have just studied IT-related behaviors in different countries, supposing that each country is characterized by a different set of cultural values. Their findings can be criticized in a sense that cultural values that characterize a country could not be espoused by all the members of this country. For example, Hofstede has found that Japan is a collectivist country, but this does not mean that each Japanese person will have the same level of collectivism. Actually, Hofstede has studied work-related values at the macro level by developing national scores for each cultural value. Therefore, it is worthwhile to analyze and measure culturally espoused values when dealing with national culture at the individual level. In this study, since we are attempting to deepen our understanding of IT adoption at the individual level, we have chosen to conceptualize cultural dimensions at the individual level so that they can be integrated in TAM. The conceptual model driven by this integration is presented in Figure 1.

In the next paragraphs, we present the rationale underlying model propositions.

**Proposition 1.** Individuals espousing high-context values will have a less strong perception of IT usefulness than those holding low-context values.

Since high-context oriented individuals prefer less coded messages, the electronic communication, implying very explicit content, will not be very useful as a means of communication. It cannot inform the receiver of the context of the message. The receiver probably will seek to know more about the message by other traditional means, implying more physical cues (face expression, intonation of the voice). Martinsons and Westwood (1997) have demonstrated that the use of management information systems (MIS) in Chinese culture depends on high-context communications. “Computers do not convey the necessary richness of meaning in a high context communication environment” (Martinsons & Westwood, 1997, p. 220) Indeed, since in China, a high-context country, coding is very restricted and so messages are terse in words, using computer-based MIS will not allow a full understanding of
messages. Actually, in order to better interpret the words, the Chinese rely upon other cues such as tone, dynamics, facial expression, and body language, which are not permitted when using computer-based communication.

**Proposition 2.** Individuals adopting monochronic time values will be using IT more than those adopting polychronic time values.

Individuals adopting the monochronic time are worried about the monitoring of time and prefer doing one thing at a time; therefore, they can view in IT a way to have control over time. Rowe and Struck (1999) argued that “people who are biased towards action see in asynchronous media the way to coordinate their tasks without interrupting them” (p. 166). In this case, we could expect that e-mail or voicemail would be appreciated highly by individuals espousing monochronic cultural values. On the contrary, individuals holding more fluid attitudes toward time are able to engage in many things at once, pay more attention to interpersonal relationships than to schedules, and accept disturbances. Therefore, they will be expected to view IT as less useful compared to individuals holding monochronic values.

**Proposition 3.** Individuals in high power distance cultures accept less IT than individuals in low power distance cultures.

In high power distance cultures, IT could threaten the hierarchy, which reflects “the existential inequality between higher-ups and lower-downs” (Hofstede, 1997, p. 37), because it suggests decentralization. Conversely, in low power distance cultures, individuals are more interdependent, whatever their ranks in the hierarchy. Therefore, they will be more favorable to IT, which does not contradict their perception of power distribution. For example, in an interpretive study conducted by Hasan and Ditsa (1999) comparing IT adoption in Australia, West Africa, and the Middle East, they have found that in the Middle East, high in power distance, modern IT, like the Internet, was seen as a threat to the authoritarian structure of their society. In the same vein, Martinsons and Westwood (1997) have demonstrated through an explanatory theory that paternalism in Chinese culture is an influential factor regarding the use of computer-based MIS, compared to American culture.

Straub, Keil, and Brenner (1997), testing TAM in three countries (the U.S., Switzerland, and Ja-
Information Technology Acceptance across Cultures

Proposition 4. Masculinity/femininity moderates the relationship between perceived usefulness and system usage.

Perceived usefulness will be more determinate for system usage for individuals espousing masculine values, since the perceived usefulness of IT is related intimately to achievement values that predominate in masculine cultures. In feminine cultures, work environment and the quality of life are much more important than attaining goals; this is why we expect much less impact of perceived usefulness of IT on usage for individuals adopting feminine values. Leidner and Carlsson (1998) have found that the Mexicans, belonging to a masculine culture, show more interest in executive information systems (EIS) than the Swedes. More precisely, the Mexicans perceive EIS as more useful than the Swedes, because such a system allows increasing the speed of decision making, and therefore, work goals could be reached more easily. In addition, in masculine cultures in which individuals are highly assertive, media lacking social presence, such as e-mail, would not be favored (Straub et al., 1997), because it does not allow end users to be highly aggressive and assertive.

Proposition 5. Individualism/collectivism moderates the relationship between subjective norms and system usage.

People in individualist cultures are more concerned with themselves than with the group. Therefore, for individuals holding individualistic cultural values, the opinions of the members of the group will not have weight in their decision to adopt IT. Conversely, people holding collectivist values will be more concerned with the maintenance of the group's cohesiveness. As a result, they will be expected to show more interest in others' opinions about IT because they want to conform to the group's behavior. In a comparative study on the applicability of the TRA across two different cultural settings, Korea and the U.S., Lee and Green (1991) have found that social norms are more important for collectivistic cultures (Korea) than for individualistic ones (U.S.) in influencing behavior.

Proposition 6. Masculinity/femininity moderates the relationship between subjective norms and system usage, such as subjective norms, will have much less influence on system usage for masculinity-oriented individuals.

In feminine cultures, individuals are expected to pay more attention to the opinions of others in behaving since they are more people-oriented than in masculine cultures in which the most important thing is goal achievement.

Proposition 7. Power distance moderates the relationship between subjective norms and system usage.

In high power distance cultures, since individuals are not supposed to disagree with their superiors, their reliance upon the opinions of
superiors will be more marked when assessing IT than for individuals from low power distance cultures.

Martinsons and Westwood (1997) have demonstrated through their explanatory theory that paternalism in Chinese culture is an influential factor regarding the use of management information systems compared to American culture. Paternalism is a concept very close to high power distance, since in paternalistic societies, key decisions are made by the patriarch, and management systems are very centralized.

According to Kowner and Wiseman (2003), people in tight (vs. loose) cultures in which deviation from behavior is not permitted “are more likely to obey the behavior ascribed by their social position” (p. 182). Consequently, social influence will play a greater role in shaping IT adoption for individuals belonging to tight culture than for those belonging to loose cultures.

**Proposition 8. Uncertainty avoidance acts also as a moderator of the relationship between subjective norms and system usage.**

The social influence exerted by important persons will be much more important in determining IT use in cultures seeking to avoid uncertainty than in cultures comfortable with uncertainty. Actually, in order to deal with uncertainty and ambiguity, individuals in strong uncertainty avoidance cultures are very concerned by the establishment and respect for rules, and therefore, subjective norms will be more important as guidance to behavior than for individuals in weak uncertainty avoidance cultures that rely more on their proper competence to evaluate a situation. The process of compliance (Kelman, 1958), one of the basic processes underlying the relationship between subjective norms and behavior, will be more salient when individuals are holding high uncertainty avoidance values. Indeed, compliance supposes that the individual will conform because a social actor that is important to him or her (and having the power of reward and punishment) wants him or her to behave in a specific manner. Therefore, conforming to referent others by adopting IT will weaken the uncertainty pertaining to the nonadoption of IT.

**PRACTICAL IMPLICATIONS**

The framework we provide is an attempt to highlight the importance of culture when dealing with IT adoption in different national cultural settings. It should improve IT designers’ awareness of the importance of cultural values for IT acceptance in foreign countries. Actually, the framework we offer does not suggest prescriptions to be adopted by IT designers. Rather, it encourages the latter to take into account cultural values when designing IS and/or preparing IT implementation procedures for companies around the world. Actually, IT designers should be aware that implementation failure could be caused by cultural incompatibility. As a result, they should adapt their implementation tactics so that they will be more congruent with end users’ cultural systems. For example, in high power distance cultures, end users may be reluctant to use computer-mediated communication tools, because this use may lead them to contradict their superiors. Therefore, IT designers should adjust IT features to the social needs of end users.

Furthermore, the conceptual model we have proposed suggests that the key belief in TAM, which is the perceived usefulness of IT, has cultural antecedents. Indeed, the perceived usefulness of IT depends on the type of the context of communication (high or low) and on the type of time adopted (monochronic or polychronic). In addition, the well-established positive relationship between perceived usefulness and system usage is shown to be moderated by two cultural values; namely, power distance and masculinity/femininity. Finally, the intensity of the influence of subjective norms on system usage has been
shown to be different, depending on the cultural values espoused by the IT users. Indeed, social influence would be most salient when end users accept and expect inequality in power, do not tolerate uncertainty, are more concerned by the group than by their selves, and are people-oriented.

CONCLUSION

In this chapter, we offer a theoretical perspective on the effect of national culture on IT adoption and use. Through the conceptual model we have presented, we wanted to move beyond models considering culture as a black box and offering an ad hoc cultural explanation of IT-related behaviors. First, we have identified pertinent cultural values that could offer a fruitful explanation of differences in IT-related behaviors and beliefs across countries. Then, we have provided propositions linking these cultural values to TAM constructs and relationships. We contend that high context/low context of communication and polychronism/monochronism have a direct effect on perceived usefulness of IT; power distance and masculinity/femininity have moderator effects on the relationship between perceived usefulness and system usage and individualism/collectivism; uncertainty avoidance, masculinity/femininity, and power distance have moderator effects on the relationship between subjective norms and system usage.

In the current context of internationalization, taking into account the societal environment in the understanding of IT acceptance behavior becomes more relevant in comparison with the past. Indeed, information technologies are so ubiquitous and pervasive that one should explore more their relationship with different societal contexts varying across countries. Actually, IT that is accepted in a specific cultural context may not be accepted in the same way in another culture.

The framework presented here is a first step in better understanding the relationship between national culture and IT adoption and use. It goes without saying that this conceptual model needs to be empirically tested. A field study research involving samples from different countries should be conducted.

Chapter 1.12
Is Information Ethics Culture–Relative?

Philip Brey
University of Twente, The Netherlands

ABSTRACT
In this article, I examine whether information ethics is culture relative. If it is, different approaches to information ethics are required in different cultures and societies. This would have major implications for the current, predominantly Western approach to information ethics. If it is not, there must be concepts and principles of information ethics that have universal validity. What would they be? The descriptive evidence is for the cultural relativity of information ethics will be studied by examining cultural differences between ethical attitudes towards privacy, freedom of information, and intellectual property rights in Western and non-Western cultures. I then analyze what the implications of these findings are for the metaethical question of whether moral claims must be justified differently in different cultures. Finally, I evaluate what the implications are for the practice of information ethics in a cross-cultural context.

INTRODUCTION
Information ethics has so far mainly been a topic of research and debate in Western countries, and has mainly been studied by Western scholars. There is, however, increasing interest in information ethics in non-Western countries like Japan, China, and India, and there have been recent attempts to raise cross-cultural issues in information ethics (e.g., Ess, 2002; Gorniak-Kocikowska, 1996; Mizutani, Dorsey & Moor, 2004). Interactions between scholars of Western and non-Western countries have brought significant differences to light between the way in which they approach issues in information ethics. This raises the question whether different cultures require a different information ethics and whether concepts and approaches in Western information ethics can be validly applied to the moral dilemmas of non-Western cultures. In other words, is information ethics culturally relative or are there concepts and principles of information ethics that have universal validity? The aim of this essay is to arrive at preliminary answers to this question.
MORAL RELATIVISM AND INFORMATION ETHICS

In discussions of moral relativism, a distinction is commonly made between descriptive and metaethical moral relativism. Descriptive moral relativism is the position that as a matter of empirical fact, there is extensive diversity between the values and moral principles of societies, groups, cultures, historical periods, or individuals. Existing differences in moral values, it is claimed, are not superficial but profound, and extend to core moral values and principles. Descriptive moral relativism is an empirical thesis that can in principle be supported or refuted through psychological, sociological, and anthropological investigations. The opposite of descriptive moral relativism is descriptive moral absolutism, the thesis that there are no profound moral disagreements exist between societies, groups, cultures, or individuals. At issue in this essay will be a specific version of descriptive moral relativism, descriptive cultural relativism, according to which there are major differences between the moral principles of different cultures.

Much more controversial than the thesis of descriptive moral relativism is the thesis of metaethical moral relativism, according to which the truth or justification of moral judgments is not absolute or objective, but relative to societies, groups, cultures, historical periods, or individuals. Whereas a descriptive relativist could make the empirical observation that one society, polygamy, is considered moral whereas in another it is considered immoral, a metaethical relativist could make the more far-reaching claim that the statement “polygamy is morally wrong” is true or justified in some societies while false or unjustified in others. Descriptive relativism therefore makes claims about the values that different people or societies actually have, whereas metaethical relativism makes claims about the values that they are justified in having. Metaethical moral relativism is antithetical to metaethical moral absolutism, the thesis that regardless of any existing differences between moral values in different cultures, societies, or individuals, there are moral principles that are absolute or objective, and that are universally true across cultures, societies, or individuals. Metaethical moral absolutism would therefore hold that the statement “polygamy is morally wrong” is either universally true or universally false; it cannot be true for some cultures or societies but false for others. If the statement is true, then societies that hold that polygamy is moral are in error, and if it is false, then the mistake lies with societies that condemn it.

The question being investigated in this essay is whether information ethics is culturally relative. In answering this question, it has to be kept in mind that the principal aims of information ethics are not descriptive, but normative and evaluative. That is, its principal aim is not to describe existing morality regarding information but rather to morally evaluate information practices and to prescribe and justify moral standards and principles for practices involving the production, consumption, or processing of information. A claim that information ethics is culturally relative therefore a claim that metaethical moral relativism is true for information ethics. It is to claim that the ethical values, principles, and judgments of information ethics are valid only relative to a particular culture, presumably the culture in which they have been developed. Since information ethics is largely a product of the West, an affirmation of the cultural relativity of information ethics means that its values and principles do not straightforwardly apply to non-Western cultures.

But if the cultural relativity of information ethics depends on the truth of metaethical relativism, does any consideration need to be given to descriptive relativism for information ethics? This question should be answered affirmatively. Defenses of metaethical relativism usually depend on previous observations that descriptive relativism is true. If descriptive relativism is false, it follows that people across the world share a moral
framework of basic values and principles. But if this is the case, then it seems pointless to argue for metaethical moral relativism: why claim that the truth of moral judgments is different for different groups if these groups already agree on basic moral values? On the other hand, if descriptive relativism is true, then attempts to declare particular moral principles of judgments to be universally valid come under scrutiny. Extensive justification would be required for any attempt to adopt a particular moral framework (say, Western information ethics) as one that is universally valid. In the next section, I will therefore focus on the question whether there are good reasons to believe that there are deep and widespread moral disagreements about central values and principles in information ethics across cultures, and whether therefore descriptive cultural relativism is true for information ethics.

THE DESCRIPTIVE CULTURAL RELATIVITY OF INFORMATION-RELATED VALUES

In this section, I will investigate the descriptive cultural relativity of three values that are the topic of many studies in information ethics: privacy, intellectual property, and freedom of information. Arguments have been made that these values are distinctly Western, and are not universally accepted across different cultures. In what follows I will investigate whether these claims seem warranted by empirical evidence. I will also relate the outcome of my investigations to discussions of more general differences between Western and non-Western systems of morality.

How can it be determined that cultures have fundamentally different value systems regarding notions like privacy and intellectual property? I propose that three kinds of evidence are relevant:

1. **Conceptual**: the extent to which there are moral concepts across cultures with similar meanings. For example, does Chinese culture have a concept of privacy that is similar to the American concept of privacy?

2. **Institutional**: the extent to which there is similarity between codified rules that express moral principles and codified statements that express moral judgments about particular (types of) situations. For example, are the moral principles exhibited in the laws and written rules employed in Latin cultures on the topic of privacy sufficiently similar to American laws and rules that it can be claimed that they embody similar moral principles?

3. **Behavioral**: the similarity between customs and behaviors that appear to be guided by moral principles. This would include tendencies to avoid behaviors that are immoral regarding a moral principle, tendencies to show disapproval to those who engage in such behaviors, and to show disapproval to those who do not, and tendencies to show remorse or guilt when engaging in such behaviors. For instance, if a culture has a shared privacy principle that states that peeking inside someone’s purse is wrong, then it can be expected that most people try not to do this, disapprove of those who do, and feel ashamed or remorseful when they are caught doing it.

It is conceivable that in a particular culture a value or moral principle is widely upheld at the behavioral level, but has not (yet) been codified at the institutional and conceptual level. But this is perhaps unlikely in cultures with institutions that include extensive systems of codified rules, which would include any culture with a modern legal system. It is also conceivable that a moral value or principle is embodied in both behavioral customs and codified rules, but no good match can be found at the conceptual level. In that case,
it seems reasonable to assume that the value or principle at issue is embodied in the culture, but different concepts are used to express it, making it difficult to find direct translations.

A full consideration of the evidence for descriptive moral relativism along these three lines is beyond the scope of this article. I only intend to consider enough evidence to arrive at a preliminary assessment of the cultural relativity of values in contemporary information ethics.

Privacy

It has been claimed that in Asian cultures like China and Japan, no genuine concept or value of privacy exists. These cultures have been held to value the collective over the individual. Privacy is an individual right, and such a right may not be recognized in a culture where collective interest tend to take priority over individual interests. Using the three criteria outline above, and drawing from studies of privacy in Japan, China and Thailand, I will now consider whether this conclusion is warranted.

At the conceptual level, there are words in Japanese, Chinese, and Thai that refer to a private sphere, but these words seem to have substantially different meanings than the English word for privacy. Mizutani et al. (2004) have argued that there is no word for “privacy” in traditional Japanese. Modern Japanese, they claim, sometimes adopt a Japanese translation for the Western word for privacy, which sounds like “puraibashii”, and written in katakana. Katakana is the Japanese phonetic syllabary that is mostly used for words of foreign origin. According to Nakada and Tamura (2005), Japanese does include a word for “private”, “Watakusi”, which means “partial, secret and selfish”. It is opposed to “Ohyake”, which means “public”. Things that are Watakusi are considered less worthy than things that are Ohyake. Mizutani et al. (2004) point out, in addition, that there are certainly behavioral customs in Japan that amount to a respect for privacy. There are conventions that restrict access to information, places, or objects. For example, one is not supposed to look under clothes on public streets.

In China, the word closest to the English “privacy” is “Yinsi”, which means “shameful secret” and is usually associated with negative, shameful things. Lü (2005) claims that only recently that “Yinsi” has also come to take broader meanings to include personal information, shameful or not, that people do not want others to know (see also Jingchun, 2005; McDougall & Hansson, 2002). This shift in meaning has occurred under Western influences. As for institutional encoding of privacy principles, Lü maintains that there currently are no laws in China that protect an individual right to privacy, and the legal protection of privacy has been weak and is still limited, though there have been improvements in privacy protection since the 1980s.

Kitiyadisai (2005), finally, holds that the concept of privacy does not exist in Thailand. She claims that the Western word privacy was adopted in the late nineteenth or early twentieth century in Thailand, being transliterated as “privade,” but this word gained a distinctly Thai meaning, being understood as a collectivist rather than an individual notion. It referred to a private sphere in which casual dress could be worn, as opposed to a public sphere in which respectable dress had to be worn. In the Thai legal system, Kitiyadisai claims there has not been any right to privacy since the introduction of privacy legislation in 1997 and a Thai constitution, also in 1997, that for the first time guarantees basic human rights. Kitiyadisai argues, however, that Thai privacy laws are hardly enacted in practice, and many Thais remain unaware of the notion of privacy.

It can be tentatively concluded that the introduction of a concept of privacy similar to the Western notion has only taken place recently in Japan, China, and Thailand, and that privacy legislation has only taken place recently. In traditional
Japanese, Chinese, and Thai culture, which still has a strong presence today, distinctions are made that resemble the Western distinction between public and private, and customs exist that may be interpreted as respective of privacy, but there is no recognized individual right to privacy.

**Intellectual Property Rights**

In discussing the cultural relativity of intellectual property rights (IPR), I will limit myself to one example: China. China is known for not having a developed notion of private or individual property. Under communist rule, the dominant notion of property was collective. All means of production, such as farms and factories, were to be collectively owned and operated. Moreover, the state exercised strict control over the means of production and over both the public and private sphere. A modern notion of private property was only introduced since the late 1980s. Milestones were a 1988 constitutional revision that allowed for private ownership of means of production and a 2004 constitutional amendment that protects citizens from encroachment of private property.

The notion of intellectual property has only recently been introduced in China, in the wake of China’s recent economic reforms and increased economic interaction with the West. China is currently passing IPR laws and cracking down on violations of IPR in order to harmonize the Chinese economic system with the rest of the world. But as journalist Ben Worthen observes, “the average citizen in China has no need and little regard for intellectual property. IPR is not something that people grew up with … and the percent of citizens who learn about it by engaging in international commerce is tiny.” Worthen also points out that Chinese companies “have no incentive to respect IPR unless they are doing work for Western companies that demand it” and that “since most of the intellectual property royalties are headed out of China there isn’t a lot of incentive for the government to crack down on companies that choose to ignore IPR.”

All in all, it can be concluded that China’s value system traditionally has not included a recognition of intellectual property rights, and it is currently struggling with this concept.

**Freedom of Information**

Freedom of information is often held to comprise two principles: freedom of speech (the freedom to express one’s opinions or ideas, in speech or in writing) and freedom of access to information. Sometimes, freedom of the press (the freedom to express oneself through publication and dissemination) is distinguished as a third principle. In Western countries, freedom of information is often defined as a constitutional and inalienable right. Laws protective of freedom of information are often especially designed to ensure that individuals can exercise this freedom without governmental interference or constraint. Government censorship or interference is only permitted in extreme situations, pertaining to such things as hate speech, libel, copyright violations, and information that could undermine national security.

In many non-Western countries, freedom of information is not a guiding principle. There are few institutionalized protections of freedom of information; there are many practices that interfere with freedom of information, and a concept of freedom of information is not part of the established discourse in society. In such societies, the national interest takes precedence, and an independent right to freedom information either is not recognized or is made so subordinate to national interests that it hardly resembles the Western right to freedom of information. These are countries in which practices of state censorship are widespread; mass media are largely or wholly government-controlled, the Internet, databases, and libraries are censored, and messages that do not conform to the party line are cracked down upon.

Let us, as an example, consider the extent to which freedom of information can be said to be a value in Chinese society. Until the 1980s, the
idea of individual rights or civil rights was not a
well-known concept in China. Government was
thought to exist to ensure a stable society and a
prosperous economy. It was not believed to have
a function to protect individual rights against col-
clective and state interests. As a consequence of
this general orientation, the idea of an individual
right to freedom of information was virtually
unknown. Only recently has China introduced
comprehensive civil rights legislation. In its 1982
constitution, China introduced constitutional
principles of freedom of speech and of the press.
And in 1997, it signed the International Conven-
tion on Economic, Social, and Cultural Rights,
and in 1998 the International Convention on Civil
and Political Rights (the latter of which it has not
yet ratified).

Even though the Chinese government has
recently come to recognize a right to freedom of
information, as well as individual human rights
in general, and has introduced legislation to this
effect, state censorship is still rampant, and the
principle of upholding state interest still tends to
dominate the principle of protecting individual
human rights. Internet censorship presents a good
example of this. Internet traffic in China is con-
trolled through what the Chinese call the Golden
Shield, and what is known outside mainland China
as the Great Firewall of China. This is a system
of control in which Internet content is blocked by
routers, as well as at the backbone and ISP level,
through the “filtering” of undesirable URLs and
keywords. A long list of such “forbidden” URLs
and keywords has been composed by the Chinese
State Council Information Office, in collaboration
with the Communist Party’s Propaganda Depart-
ment. This system is especially geared towards
censorship of content coming from outside main-
land China (Human Rights Watch, 2006).

Rights-Centered and
Virtue-Centered Morality

A recurring theme in the above three discussions
has been the absence of a strong tradition of individual
rights in the cultures that were discussed—those of China, Japan, and Thailand—and the
priority that is given to collective and state interests. Only very recently have China, Japan, and
Thailand introduced comprehensive human rights
legislation, which has occurred mainly through
Western influence, and there is still considerable
tension in these societies, especially in China
and Thailand, between values that prioritize the
collective and the state and values that prioritize
the individual.

Various authors have attempted to explain the
worldview that underlies the value system of these
countries. In Japan and Thailand, and to a lesser
extent China, Buddhism is key to an understanding
of attitudes towards individual rights. Buddhism
holds a conception of the self that is antithetical
to the Western conception of an autonomous
self which aspires to self-realization. Buddhism
holds that the self does not exist and that human
desires are delusional. The highest state that hu-
mans can reach is Nirvana, a state of peace and
contentment in which all suffering has ended. To
reach Nirvana, humans have to become detached
from their desires, and realize that the notion of
an integrated and permanent self is an illusion. In
Buddhism, the self is defined as fluid, situation-
dependent, and ever-changing. As Mizutani et al.
and Kitiyadisai have noted, such a notion of the
self is at odds with a Western notion of privacy
and of human rights in general, notions which
presuppose a situation-independent, autonomous
self which pursues its own self-interests and which
has inalienable rights that have to be defended
against external threats.

In part through Buddhism, but also through
the influence of other systems of belief such as
Confucianism, Taoism, and Maoism, societies
Is Information Ethics Culture-Relative?

like those of China and Thailand have developed a value system in which the rights or interests of the individual are subordinate to those of the collective and the state. To do good is to further the interests of the collective. Such furtherances of collective interests will generally also benefit the individual. The task of government, then, is to ensure that society as a whole functions well, in a harmonious and orderly way, and that social ills are cured, rather than the ills of single individuals. In other words, government works for the common good, and not for the individual good.

Only recently have countries like China and Thailand come to recognize individual human rights and individual interests next to collective interests. But according to Lü (2005), the collectivist ethic still prevails:

Adapting to the demands of social diversity, the predominant ethics now express a new viewpoint that argues against the simple denial of individual interests and emphasizes instead the dialectical unification of collective interests and individual interests: in doing so, however, this ethics points out that this kind of unification must take collective interests as the foundation. That is to say, in the light of the collectivism principle of the prevailing ethics, collective interests and individual interests are both important, but comparatively speaking, the collective interests are more important than individual interests. (Lü, 2005, p. 12)

If this observation is correct, then the introduction of human rights legislation and property rights in countries like China is perhaps not motivated by a genuine recognition of inalienable individual human rights, but rather a recognition that in the current international climate, it is better to introduce human rights and property rights, because such principles will lead to greater economic prosperity, which is ultimately to the benefit of the collective.

The dominant value systems prevalent in China, Thailand, and Japan are examples of what philosopher David Wong (1984) has called virtue-centered moralities. According to Wong, at least two different approaches to morality can be found in the world: a virtue-centered morality that emphasizes the good of the community, and a rights-centered morality that stresses the value of individual freedom. Rights-centered morality is the province of the modern West, although it is also establishing footholds in other parts of the world. Virtue-centered morality can be found in traditional cultures such as can be found in southern and eastern Asia and in Africa. Wong’s distinction corresponds with the frequently made distinction between individualist and collectivist culture, that is found, amongst others, in Geert Hofstede’s (1991) well-known five-dimensional model of cultural difference. However, this latter distinction focuses on social systems and cultural practices, whereas Wong makes a distinction based in differences in moral systems.

In Wong’s conception of virtue-centered moralities, individuals have duties and responsibilities that stem from the central value of a common good. The common good is conceived of in terms of an ideal conception of community life, which is based on a well-balanced social order in which every member of the community has different duties and different virtues to promote the common good. Some duties and virtues may be shared by all members. The idea that human beings have individual rights is difficult to maintain in this kind of value system, because recognition of such rights would have to find its basis in the higher ideal of the common good. But it seems clear that attributing rights to individuals is not always to the benefit of the common good. The recognition of individual property rights, for example, could result in individual property owners not sharing valuable resources that would benefit the whole community. In virtue-centered moralities, the ideal is for individuals to be virtuous, and virtuous individuals are those individuals whose individual good coincides with their contribution to the common good. Individual goods may be recog-
Is Information Ethics Culture-Relative?

Individuals deserve respect only because of their perceived contribution to the common good, not because they possess inalienable individual rights.

Conclusion

The discussion of privacy, intellectual property rights, and freedom of information has shown that a good case can be made for the descriptive cultural relativity of these values. These values are central in information ethics, as it has been developed in the West. Moreover, it was argued that the uncovered cultural differences in the appraisal of these values can be placed in the context of a dichotomy between two fundamentally different kinds of value systems that exist in different societies: rights-centered and virtue-centered systems of value. Information ethics, as it has developed in the West, has a strong emphasis on rights, and little attention is paid to the kinds of moral concerns that may exist in virtue-centered systems of morality. In sum, it seems that the values that are of central concern in Western information ethics are not the values that are central in many non-Western systems of morality. The conclusion therefore seems warranted that descriptive moral relativism is true for information ethics.

Two Standard Arguments for Metaethical Relativism

There are two traditional arguments for metaethical moral relativism that rely on the truth of descriptive moral relativism (Wong, 1993). The one most frequently alluded to is the argument from diversity. This argument starts with the observation that different cultures employ widely different moral standards. Without introducing additional premises, the argument goes on to conclude that therefore, there are no universal moral standards. This argument rests on what is known in philosophy as a naturalistic fallacy, an attempt to derive a norm from a fact, or an “ought” from an “is”. The premise of the argument is descriptive: there are different moral standards. The conclusion is normative: no moral standard has universal validity. No evidence has been presented that the truth of the premise has any bearing on the truth of the conclusion.

A second, stronger argument for moral relativism is the argument from functional necessity, according to which certain ethical beliefs in a society may be so central to its functioning that they cannot be given up without destroying the society. Consequently, the argument runs, these ethical beliefs are true for that society, but not necessarily in another. However, this argument is also problematic because it grounds the truth of ethical statements in their practical value for maintaining social order in a particular society. Such a standard of justification for ethical statements is clearly too narrow, as it could be used to justify the moral beliefs of societies whose beliefs and practices are clearly unethical, for instance, fascist societies. If a society operates in a fundamentally unethical way, then the transformation of some of its social structures and cultural forms would seem acceptable if more ethical practices are the result.
Wong’s and Harman’s Argument for
Metaethical Relativism

More convincing arguments for moral relativism have been presented by David Wong (1984, 2006) and Gilbert Harman (1996, 2000). Their argument runs, in broad outline, as follows. There are deep-seated differences in moral belief between different cultures. Careful consideration of the reasons for these moral beliefs they have shown that they are elements of different strategies to realize related but different conceptions of the Good. No good arguments can be given why one of these conceptions of the Good is significantly better than all the others. Therefore, these moral beliefs are best explained as different but (roughly) equally valid strategies for attaining the Good.

This is a much better argument than the previous two, since it puts the ball in the metaethical absolutist’s court: he will have to come up with proof that it is possible to provide good arguments for the superiority of one particular conception of the Good over all other conceptions. Metaethical absolutists can respond to this challenge in two ways. First, they may choose to bite the bullet and claim that a rational comparison of different conceptions of the Good is indeed possible. Different conceptions of the Good, they may argue, rely on factual or logical presuppositions that may be shown to be false. Alternatively, they may argue that there are universally shared moral intuitions about what is good, and these intuitions can be appealed to in defending or discrediting particular conceptions of the Good. For instance an individual who believes that physical pleasure is the highest good could conceivably be persuaded to abandon this belief through exposure to arguments that purport to demonstrate that there are other goods overlooked by this individual that are at least as valuable. Such an argument could conceivably rely on someone’s moral intuitions about the Good that could be shown to deviate from someone’s explicit concept of the Good.

Second, a mixed position could be proposed, according to which it is conceded that individuals or cultures may hold different conceptions of the Good that cannot be rationally criticized (pace metaethical relativism) but that rational criticism of individual moral beliefs is nevertheless possible (pace metaethical absolutism) because these beliefs can be evaluated for their effectiveness in realizing the Good in which service they stand. After all, if moral beliefs are strategies to realize a particular conception of the Good, as Wong and Harman have argued, then they can be suboptimal in doing so. A belief that Internet censorship is justified because it contributes to a more stable and orderly society can be wrong because it may not in fact contribute to a more stable and orderly society. Empirical arguments may be made that Internet censorship is not necessary for the maintenance of social order, or even that Internet censorship may ultimately work to undermine social order, for example, because it creates discontentment and resistance.

In the existing dialogue between proponents of rights-centered and virtue-centered systems of morality, it appears that both these approaches are already being taken. Western scholars have criticized the organicist conception of society that underlies conceptions of the Good in many Asian cultures, while Western definitions of the Good in terms of individual well-being have been criticized for their atomistic conception of individuals. Rights-based systems of morality have been criticized for undervaluing the common good, whereas virtue-based systems have been criticized for overlooking the importance of the individual good. In addition, both rights-centered and virtue-centered systems of morality have been criticized for not being successful by their own standards. Western individualism has been claimed to promote selfishness and strife, which results in many unhappy individuals plagued by avarice, poverty, depression, and loneliness. Western societies have therefore been claimed to be unsuccessful in attaining their own notion of the Good, defined in terms of individual well-be-
Is Information Ethics Culture-Relative?

Virtue-centered cultures have been claimed to have difficulty in developing strong economies that serve the common good, because good economies have been argued to require private enterprise and a more individualist culture. In addition, strong state control, which is a feature of many virtue-centered cultures, has been argued to lead to corruption and totalitarianism, which also do not serve the common good.

In light of the preceding observations, it seems warranted to conclude, pace metaethical absolutism, that rational criticism between different moral systems is possible. It does not follow, however, that conclusive arguments for universal moral truths or the superiority of one particular moral system over others are going to be possible. Critics of a particular moral system may succeed in convincing its adherents that the system has its flaws and needs to be modified, but it could well be that no amount of criticism ever succeeds in convincing its adherents to abandon core moral beliefs within that system, however rational and open-minded these adherents are in listening to such criticism.

Conclusion

I have argued, pace metaethical relativism, that it is difficult if not impossible to provide compelling arguments for the superiority of different notions of the Good that are central in different moral systems, and by implication, that it is difficult to present conclusive arguments for the universal truth of particular moral principles and beliefs. I have also argued, pace metaethical absolutism, that is nevertheless possible to develop rational arguments for and against particular moral values and overarching conceptions of the Good across moral systems, even if such arguments do not result in proofs of the superiority of one particular moral system or moral principle over another.

From these two metaethical claims, a normative position can be derived concerning the way in which cross-cultural ethics ought to take place. It follows, first of all, that it is only justified for proponents of a particular moral value or principle to claim that it ought to be accepted in another culture if they make this claim on the basis of a thorough understanding of the moral system operative in this other culture. The proponent would have to understand how this moral system functions and what notion of the Good it services, and would have to have strong arguments that either the exogenous value would be a good addition to the moral system in helping to bring about the Good serviced in that moral system, or that the notion of the Good serviced in that culture is flawed and requires revisions. In the next section, I will consider implications of this position for the practice of information ethics in cross-cultural settings.

INFORMATION ETHICS IN A CROSS-CULTURAL CONTEXT

It is an outcome of the preceding sections that significant differences exist between moral systems of different cultures, that these differences have important implications for moral attitudes towards uses of information and information technology, and that there are good reasons to take such differences seriously in normative studies in information ethics. In this section, I will argue, following Rafael Capurro, that we need an intercultural information ethics that studies and evaluates cultural differences in moral attitudes towards information and information technology. I will also critically evaluate the claim that the Internet will enable a new global ethic that provides a unified moral framework for all cultures.

Intercultural Information Ethics

The notion of an intercultural information ethics (IIE) was first introduced by Rafael Capurro (2005, in press), who defined it as a field of research in which moral questions regarding information
technology and the use of information are reflected on in a comparative manner on the basis of different cultural traditions. I will adopt Capurro’s definition, but differ with him on what the central tasks of an IIE should be. Capurro defines the tasks of IIE very broadly. For him, they not only the comparative study of value systems in different cultures in relation to their use of information and information technology, but also studies of the effect of information technology on customs, languages, and everyday problems, the changes produced by the Internet on traditional media, and the economic impact of the Internet to the extent that it can become an instrument of cultural oppression and colonialism.

I hold, in contrast, that studies of the effects of information technology in non-Western cultures are more appropriately delegated to the social sciences (including communication studies, cultural studies, anthropology and science, and technology studies). An intercultural information ethics should primarily focus on the comparative study of moral systems. Its overall aim would be to interpret, compare, and critically evaluate moral systems in different cultures in relation to their moral attitudes towards and behavior towards information and information technology.

This task for IIE can be broken down into four subtasks, the first two of which are exercises in descriptive ethics and the latter two of which belong to normative ethics. First, IIE should engage in interpretive studies of moral systems in particular cultures, including the systems of value contained in the religious and political ideologies that are dominant in these cultures. The primary focus in such interpretive studies within the context of IIE should be on resulting moral attitudes towards the use and implications of information technology and on the moral problems generated by uses of information technology within the context of the prevailing moral system. Second, IIE should engage in comparative studies of moral systems from different cultures, and arrive at analyses of both similarities and differences in the way that these moral systems are organized and operate, with a specific focus on the way in which they have different moral attitudes towards implications of information technology and on differences in moral problems generated by the use of information technology.

Third, IIE should engage in critical studies in which the moral systems of particular cultures are criticized based on the insights gained through the interpretive and comparative studies alluded to above, particularly in their dealings with information technology. Critical studies may be directed towards criticizing moral values and beliefs in cultures other than one’s own, and proposing modifications in the culture’s moral system and ways in which it should solve moral problems, but may also involve self-criticism, in which one’s own moral values and the moral system of one’s own culture is criticized based on insights gained from the study of alternative moral systems. Fourth, IIE should engage in interrelational studies that focus on the construction of normative models for interaction between cultures in their dealings with information and information technology that respect their different moral systems. Interrelational studies hence investigate what moral compromises cultures can make and ought to make in their interactions and what shared moral principles can be constructed to govern their interactions.

Global Ethics and the Information Revolution

Some authors have argued that globalization and the emergence of the Internet have created a global community, and that this community requires its own moral system that transcends and unifies the moral systems of all cultures and nations that participate in this global community. The ethics needed for the construction of such a moral system has been called global ethics. The idea of a global ethics or ethic was first introduced by German theologian Hans Küng in 1990 and later
elaborated by him in a book (Küng, 2001). His aim was to work towards a shared moral framework for humanity that would contain a minimal consensus concerning binding values and moral principles that could be invoked by members of a global community in order to overcome differences and avoid conflict.

Krystyna Górniak-Kocikowska (1996) has argued that the computer revolution that has taken place has made it clear that a future global ethic will have to be a computer ethic or information ethic. As she explains, actions in cyberspace are not local, and therefore the ethical rules governing such actions cannot be rooted in a particular local culture. Therefore, unifying ethical rules have to be constructed in cyberspace that can serve as a new global ethic. Similar arguments have been presented by Bao and Xiang (2006) and De George (2006).

No one would deny that a global ethic, as proposed by Küng, would be desirable. The construction of an explicit, shared moral framework that would bind all nations and cultures would evidently be immensely valuable. It should be obvious, however, that such a framework could only develop as an addition to existing local moral systems, not as a replacement of them. It would be a framework designed to help solve global problems, and would exist next to the local moral systems that people use to solve their local problems. In addition, it remains to be seen if cross-cultural interactions over the Internet yield more than a mere set of rules for conduct online, a global netiquette, and will result in a global ethic that can serve as a common moral framework for intercultural dialogue and joint action. Hongladarom (2001) has concluded, based on empirical studies, that the Internet does not create a worldwide monolithic culture but rather reduplicates existing cultural boundaries. It does create an umbrella cosmopolitan culture to some extent, but only for those Internet users who engage in cross-cultural dialogue, which is a minority, and this umbrella culture is rather superficial. Claims that the Internet will enable a new global ethic may therefore be somewhat premature. In any case, such intercultural dialogue online will have to be supplemented with serious academic work in intercultural information ethics, as well as intercultural ethics at large.

**CONCLUSION**

It was found in this essay that very different moral attitudes exist in Western and non-Western countries regarding three key issues in information ethics: privacy, intellectual property, and freedom of information. In non-Western countries like China, Japan, and Thailand, there is no strong recognition of individual rights in relation to these three issues. These differences were analyzed in the context of a difference, proposed by philosopher David Wong, between rights-centered moralities that dominate in the West and virtue-centered moralities that prevail in traditional cultures, including those in South and East Asia. It was then argued that cross-cultural normative ethics cannot be practiced without a thorough understanding of the prevailing moral system in the culture that is being addressed. When such an understanding has been attained, scholars can proceed to engage in moral criticism of practices in the culture and propose standards and solutions to moral problems. It was argued, following Rafael Capurro, that we need an intercultural information ethics that engages in interpretive, comparative, and normative studies of moral problems and issues in information ethics in different cultures. It is to be hoped that researchers in both Western and non-Western countries will take up this challenge and engage in collaborative studies and dialogue on an issue that may be of key importance to future international relations.

Is Information Ethics Culture-Relative?

ENDNOTES

1 By information ethics I mean the study of ethical issues in the use of information and information technology. Contemporary information ethics is a result of the digital revolution (or information revolution) and focuses mainly on ethical issues in the production, use, and dissemination of digital information and information technologies. It encloses the field of computer ethics (Johnson, 2000) as well as concerns that belong to classical information ethics (which was a branch of library and information science), media ethics, and journalism ethics.

2 This doctrine is called metaethical rather than normative because it does not make any normative claims, but rather makes claims about the nature of moral judgments. *Normative moral relativism* would be the thesis that it is morally wrong to judge or interfere with the moral practices of societies, groups, cultures, or individuals who have moral values different from one’s own. This is a normative thesis because it makes prescriptions for behavior.

Chapter 1.13
Personalization Techniques and Their Application

Juergen Anke
Dresden University of Technology, Germany

David Sundaram
University of Auckland, New Zealand

INTRODUCTION

Personalization is an approach to increase the usability of complex information systems and present the user with a comprehensible interface that is tailored to his or her needs and interests. In this article, we examine general techniques that are employed to achieve the personalization of Web sites. This is followed by a presentation of real-world examples. It will be shown how different levels of personalization can be achieved by employing the discussed techniques. This leads finally to a summary of the current state in personalization technologies and the issues connected with them. The article closes with some ideas on further research and development, and a conclusion.

In general, the concept of personalization refers to the ability of tailoring standardized items to the needs of individual people. It is originally derived from the ideas of Pine (1993) who proposed that companies should move from the paradigms of standardized products and homogeneous markets to customizable products that meet the requirements of many different customers. The principle of mass customization applies to a certain degree to most car manufacturers and some computer manufacturers, for example, Dell.

In the digital world of the World Wide Web, the degree of customization can be much higher than in the physical world. Currently, a number of online portals and e-commerce shops make use of personalization to provide a better user experience. Although Web sites may be the most popular examples of personalization, the concept is not limited to the Web. Every information system that deals with large amounts of data and/or has a heterogeneous group of users can benefit from it. Examples include e-learning environments, electronic books, computer-operated voice and telephony services, and tourist guides.

Personalization is also very useful for mobile devices like personal digital assistants (PDAs) or mobile phones (cf, Mulvenna, Anand, & Buchner,
2000). Technologies like mobile Internet access, WAP (Wireless Application Protocol), and future multimedia applications based on high-capacity wireless technologies require the designers of services for these devices to deal with limited input capabilities and small display sizes. For that reason, every method that assists the user in navigating and finding information easily adds real value to applications for such devices.

PERSONALIZATION TECHNIQUES

The core idea of personalization is to customize the presentation of information specifically to the user to make user interfaces more intuitive and easier to understand, and to reduce information overload.

The main areas of tailoring presentation to individual users are content and navigation. Content refers to the information being displayed, and navigation refers to the structure of the links that allow the user to move from one page to another. Personalized navigation can help the user to easily find what he or she is looking for or to discover new information. For example, a system discussed by Belkin (2000) assists users in refining search queries by giving recommendations on related or similar terms.

Adaptable vs. Adaptive

There are two approaches to achieve personalization: adaptable and adaptive methods. The former is a term for systems that can be customized by the user in an explicit manner; that is, the user can change the content, layout, appearance, and so forth to his or her needs. This data is called a user profile, and all personalized presentation is based on data the user provided for configuration purposes. It is important to note that the customized appearance does not change over time until the user decides to change his or her preferences.

In contrast, adaptive methods change the presentation implicitly by using secondary data. This data can be obtained from a variety of sources, for example, from the user’s actions, from the behaviour of other users on that site, or based on the currently displayed content. Methods that use this data as input are discussed in detail below. The most distinctive characteristic of adaptive methods is that they are constantly monitoring the user’s activities to adjust the arrangement and selection of relevant information.

Adaptive methods or machine-learning algorithms are huge steps toward automated customization. Current static interfaces suffer from the fact that the designer has to anticipate the needs, interests, and previous knowledge of the users in advance. As these preferences change over time, customization that requires human interaction for collecting and identifying preferences leads quickly to outdated user profiles.

Table 1 shows how adaptive and adaptable methods can be applied to customize content and navigation. The examples given are intended to be generic; more concrete examples are examined in the case studies below.

Degree of Personalization

Another important criterion for classification is the degree of personalization. Systems can have transient or persistent personalization, or be non-persnalized. With transient personalization, the customization remains temporary and is largely based on a combination of the user’s navigation and an item-to-item correlation. For example, if an item is selected, the system attaches similar items as recommendations to it whereby the content of the shopping cart is taken into consideration.

Persistent personalization systems maintain a permanent user account for every user to preserve his or her settings and preferences across separate sessions. Although this raises privacy issues and is the most difficult to implement, it offers the greatest benefit. These systems can make use
of user-to-user correlation algorithms and thus provide higher accuracy.

Another technology that belongs to the broad area of personalization is recommender systems (Mulvenna et al., 2000). Whereas straight personalization tailors just the presentation of information, recommender systems support the user in discovering new information. As recommendation relies on user preferences and interests, it is often part of personalized systems. From another perspective, one can say that recommender systems provide a selection of the most suitable content for the user. The application of recommender systems to e-commerce is discussed by Schafer, Konstan, and Riedl (2001).

In the following sections, we look at two cases that highlight the adaptive and adaptable approaches to personalization.

<table>

</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Adaptive</th>
<th>Content</th>
<th>Navigation</th>
</tr>
</thead>
<tbody>
<tr>
<td>- present the user new items which are related to the current items (recommendations)</td>
<td>- hiding unsuitable links based on the context</td>
<td></td>
</tr>
<tr>
<td>- filter content based on current actions (remove items which are dissimilar)</td>
<td>- annotate links to give meta-information about value of the linked content relating to the user’s navigation history (e.g. “no new information”, “insufficient previous knowledge” etc.)</td>
<td></td>
</tr>
</tbody>
</table>

Table 1. Application of adaptable and adaptive methods to content and navigation

APPLICATION AND IMPACT OF PERSONALIZATION: AMAZON.COM

Amazon.com is one of the pioneers of e-commerce. Originally set up as a bookstore, it has grown to a general retailer for a wide range of products. It also provides an auction platform and a marketplace where customers can sell used goods. The marketplace is seamlessly integrated into the main product catalogue, therefore customers can decide whether they want to buy a particular product as a new or a used one.

Goal

As the Amazon.com product catalogue contains more than 2 million products, users can easily get frustrated if they do not find what they are looking for. Thus, one of the main goals is to tailor the product catalogue as much as possible to the needs and interests of the user.

Aside from easy navigation, the site offers a seamlessly integrated recommendation system. It is intended to offer customers products that are either related to their interests or to the product that is currently displayed to exploit cross-selling potentials.

Personalization Techniques

Amazon.com is a highly developed online shopping site and incorporates a combination of
numerous adaptive and adaptable methods. The generated user profile is stored in a database on the server; that is, the degree of personalization is persistent.

The prevalent recommendation method is based on the purchases of other customers. It appears as a list beginning with the phrase “Customers who bought this book also bought…” on each product detail page (Figure 1a). A second list contains up to five authors whose books were bought by customers who also bought the currently selected book. Both of these features are collaborative-filtering methods of implicit collected data. Another feature called purchase circles is also a collaborative-filtering mechanism that displays the top-10 products for a particular region, institution, or company.

Other recommendation methods are based on the activities of the customer. For example, there is always one product recommendation in a sidebar that is apparently directly derived from the list of recently viewed items (Figure 1c). Moreover, there is also a recommendation page for each of the main categories (books, software, etc.) that is completely based on the customer’s purchase history.

Amazon.com also encourages customers to rate their purchased products (Figure 1e). Ratings belong to the collaborative-filtering methods. However, in contrast to the list of products other customers bought, they require explicit interaction for the sake of personalization. The ratings can also be part of customer reviews and comments. Interestingly, it is even possible to rate the ratings; that is, customers can indicate whether they found the rating helpful or not (e.g., “3 of 5 people found the following review helpful”). This mechanism is used to display the most helpful comments first and let the least helpful comments move to secondary pages.

As mentioned before, one of the goals is to exploit cross-selling potentials. One of the recent additions to Amazon.com is the “Great Buy” feature. It offers the customer the current product together with another product in a bundle at a special price (Figure 1b). The two products must have a complementary relationship to be valuable to the customer.

Outcome and Lessons Learned

Amazon.com has clearly utilized a very broad range of different personalization methods. As this site has developed constantly in product variety, functionality, and comfort, it is nearly at the state of the art in this area. The goals stated above are nearly completely fulfilled. The site is easy to navigate, the products are easy to find, and the accuracy of the recommendations seems to be very high, which animates the customer to buy further products.

The “Great Buy” feature is certainly one of the best ways to take advantage of the cross-selling potential, whereas the list of products other customers bought is more useful for the discovery of new, interesting items and navigation. The latter seems to be less accurate compared to the earlier days of the site. This might have something to do with the enormous number of customer profiles that do not provide enough distinctive attributes to form useful clusters.

Ratings and reviews can be considered as a helpful feature; however, there are a number of relatively unqualified comments. To improve the situation, the rate-the-rating feature was introduced (far after the review function itself). While this highlights the more valuable reviews, there is still room for improvement.

APPLICATION AND IMPACT OF PERSONALIZATION: YAHOO!

Yahoo! was one of the first search portals on the Web and one of the first Web sites that applied personalization on a larger scale (Manber, Patel, & Robinson, 2000). In 1996, the My Yahoo! service was introduced. It allows setting up a personal
version of Yahoo! for every user. Not only the content, but also the layout and the appearance of the page can be modified. Yahoo! is a completely adaptable system; therefore, all personalization is based on the data the user entered beforehand. The ZIP code is especially central as a lot of personalized features rely on it. The intelligence of the system lies in the ability to use this data in different situations to tailor the presentation specifically to the user.

**Goal**

The goal of Yahoo! is to bind its users by differentiating from other Web catalogues and search engines, and to provide a fully customizable and integrated portal. As the customer structure of Yahoo! is very heterogeneous, it is a good idea to offer personalization and let users construct an individual start page. Yahoo!’s service is free for
its users; money is mainly earned with advertising and revenue provisions of shopping partners. Thus, the second goal is to make advertising as effective as possible. This can be achieved by selecting banner ads that are likely to be of interest for the user.

### Personalization Techniques

Yahoo! offers an adaptable system that requires the user to explicitly provide information for personalization. The user profile is kept on a server between different visits, thus Yahoo! offers persistent personalization.

My Yahoo! enables registered users to build their own Yahoo! pages. The content is selected as so-called modules. Among the available modules are ones for weather, news, sports results, stock quotes, horoscopes, movie reviews, personal news filters, and many more. Further configuration can be done within these modules. In the example shown in Figure 2, the headline module (a) is set up to show world news from British news agencies and German Formula 1 news. The weather module (b) displays the current weather situation of selected cities only. Modules can be edited or deleted (c) directly on the page. Some of the modules offer an individual default setting that is based on the user’s area.

Not only the content, but also the layout is customizable. The chosen modules can be distributed on multiple pages that in turn consist of two or three columns where modules can be ordered arbitrarily. There are also options like colour sets and themes to change the appearance of My Yahoo!.

**Figure 2. A customized version of the My Yahoo! start page**
Outcome and Lessons Learned

The goal of flexible customization to provide an integrated portal can be considered to be fulfilled. Whether the effectiveness of advertising is increased by personalization cannot be decided with certainty since most of the literature does not mention it. However, as it is vital for Yahoo! to have effective advertising, it can be assumed that it incorporates a relatively advanced system for selecting banner advertisements on an adaptive basis.

Apart from these sophisticated personalization features, it is also essential to design high-quality default pages for people who do not want to customize at all. It turned out that only a small number of users actually customize Yahoo!: most of them take what is offered. The reasons for this may be either that the personalization tools are too complicated, or the users do not need complex personalization as the default page is satisfactory for them. Addressing all types of users also includes not requiring users to enter any personal data and not forcing them to use personalization features.

Yahoo! has decided not to use adaptive methods. They believe that these methods are still not good enough for such a complex site as a user’s behaviour is not sufficiently predictable. People must not be unsure of how the systems work; otherwise, it prevents them from experimenting as they fear breaking something. The people from Yahoo! reckon that any kind of personalization should encourage the users to experiment.

While it is beyond the scope of this article to look at the numerous other cases of personalization, it is worthwhile to mention the large-scale personalization project at ibm.com. Karat, Brodie, Karat, Vergo, and Alpert (2003) describe this in detail, and they provide an overview of the many different personalization techniques used and the reasons for selecting them for the project.

CONCLUSION

Current State of Development

A number of different approaches to personalization are currently used in various applications. Highly sophisticated e-commerce sites usually employ a combination of multiple methods and contain adaptive as well as adaptable elements in a coherent user interface. As the case study of Amazon.com has shown, organisations can add real value for the users by making it more convenient to tailor the presentation to individual needs.

Adaptive methods for personalization are very powerful means to manage information overload and simplify user interfaces. Despite their sophisticated algorithms, they can produce unpredictable and unwanted results. This is an area where further research is necessary as adaptable methods have the serious disadvantage of their configuration remaining static until the user changes it explicitly. This can be a tedious task for most users, which lowers the value even of the most flexible customization services. Hence, there are only a small number of users who actually want to customize their pages.

Directions for Future Research and Development

Improve Group-Based Personalization

The personalization based on a user’s preferences is increasingly being extended by collaborative methods. Instead of recommending items based on the profile of a single user, the system should try to take advantage of other users’ ratings and preferences as well. While this might in fact increase the accuracy of predictions, it raises the issue of proper user selection.
**Personalization Techniques and Their Application**

**New Input Methods**

Methods that allow formulating queries in a natural language rather than in special inhuman query syntax could make the interaction between the user and the system even more personalized and individualistic (Zadrozny, Budzikowska, Chai, Kambhatla, Levesque, & Nicolov, 2000).

**Combination of Explicit and Implicit Data**

Both adaptive and adaptable methods have their strengths and weaknesses, and may be more or less applicable for a particular situation. However, it seems to turn out that the combination of explicit and implicit user data provides the best results. On one hand, the effort of manual customization is minimized, and on the other hand, an adaptive method will not cause much unpredicted results when it is limited by explicit statements. Wells and Wolfers (2000) explain how customers who use online banking services need to make some basic statements about their financial goals and situations. After that, adaptive methods are used to offer financial products and services that are tailored to the customer and suitable for his or her particular needs. However, not all techniques applicable to a certain scenario will be successful in practice. Alpert, Karat, Karat, Brodie, and Vergo (2003) show in their study about users’ attitudes toward adaptive systems that users have a strong desire to always be in full control of all interaction. It is therefore important to carefully analyze the potential acceptance barriers of a designed solution before finally deploying it.

**Future Outlook**

Personalization technologies have found their way out of experimental systems of researchers into commercial applications. They are a powerful means to handle information overload, to make complex information systems more usable for a heterogeneous group of people, and to help online businesses establish personal relations with their customers (one-to-one marketing). Although we have focused on applications of personalization to Web sites, they can be used in a wide range of human-computer interactions. Personalization techniques are the key to mass customization and provide people with a much more individual experience instead of standardized services.

**REFERENCES**

Adaptable Personalization Systems: Systems that can be customized by the user in an explicit manner; that is, the user can change the content, layout, appearance, and so forth to his or her needs.

Adaptive Personalization Systems: These change the presentation implicitly by using secondary data. This data can be obtained from a variety of sources, for example, from the user’s actions, from the behaviour of other users on that site, or based on the currently displayed content.

Decision-Support Systems and Tools: In a wider sense, it can be defined as systems and tools that affect the way people make decisions.

Mass Customization: The customization of products and services for individual customers, but at a mass-production price.

Personalization: An approach to increase the usability of complex information systems and present the user with a comprehensible interface that is tailored to his or her needs and interests.

Recommender Systems: A special type of decision-support system that gives recommendations for further actions or related items.

Tailoring: In the context of personalization, it can be with respect to content or navigation. Content refers to the information being displayed, and navigation refers to the structure of the links that allow the user to move from one page to another.

User-Centered Evaluation of Personalized Web Sites: What’s Unique?

ABSTRACT
In addition to traditional usability issues, evaluation studies for personalized Web sites and applications must consider concerns specific to these systems. In the general case, usability studies for computer-based applications attempt to determine whether the software, in actual use, meets users’ needs; whether users can accomplish their goals in using the software; whether users can understand and use the application (whether they comprehend what they can do and how); the rate, frequency, and severity of user errors; the rate of and time duration for task completion; and so on. But in the case of user-centered evaluations of personalized Web sites, there are additional questions and issues that must be addressed. In this paper, we present some of these, based on our experience in usability studies of a personalized e-commerce site.

INTRODUCTION
Personalized Web sites attempt to adapt and tailor the user experience to a particular user’s preferences, needs, goals, interests, knowledge, or interaction history. A personalized site adapts its content, content structure, the presentation of information, the inclusion of hyperlinks, or the availability of functionality to each individual user’s characteristics and/or usage behavior. Such a site may place specific information, which it “thinks” you will be interested in, at a distinguished or obvious location on a Web page. Another personalized site may choose to add or
User-Centered Evaluation of Personalized Web Sites

delete specific content or hyperlinks to additional information based on what it “knows” about the current user’s knowledge or interests. An e-commerce site that knows what model laptop you own may only show accessories compatible with that model. A site that displays information about movies and theater schedules may use knowledge of the user’s postal code to display only theaters within n miles of the user’s location. A personalized news site may elect to show (or not) today’s baseball scores, depending on whether the user has viewed this sort of information in previous site visits. A book seller may use knowledge of the books you have ordered in the past to recommend new works by the same author or other authors of the same genre, or may suggest additional books purchased by other users that have bought the same book as you are now ordering. Data about the user, used to drive the site’s personalizations, may be obtained by information explicitly provided by the user and by inferences made by the system based on previous user interactions.

The personalization approach begs many questions. Do personalized Web sites actually improve the user’s experience when using such sites? Do specific personalization features improve and others detract from user experience? Does personalization actually add value to users? Is the site not only usable but acceptable, attractive, and desirable to users?

Personalized Web sites are a specific example of the more general field of adaptive systems. The literature of the evaluation of adaptive systems is replete with evaluative studies of how well the “system” works. These evaluations have focused on algorithms and user model representations for programmatically “implementing” the systems’ adaptive behavior, including determining how well the detection and gathering of implicit information about users’ functions, how appropriately are inferences drawn about users, and how robust are the systems’ techniques for using such information to provide some type of adaptive functionality. For example, evaluations of adaptive systems might consider whether the system’s inferences about the user indeed coincide with the user’s prior behavior (Weibelzahl & Weber, 2003). As another example, “evaluators need to check if [the system’s] inferences or the conclusions drawn by the system concerning the user-computer interaction are correct since it is not necessary that there will be a direct one to one mapping between raw data and their semantically meaningful counterparts” (Gupta & Grover, 2004). Thus many adaptive system evaluations focus on how well the system functions in an (objective) application-centered sense. Many such studies focus on an individual personalization technique, such as recommender systems or collaborative filtering (e.g., Mobasher, Dai, Luo, & Nakagawa, 2001; Zhu & Greiner, 2005). Still others have focused on success of a personalized site as measured by the number of site visits and return visits, number of purchases on an e-commerce site, click-throughs to suggested content, and so forth.

Of course, many of these measures are useful and must be considered in the evaluation of a personalized site. However, evaluations of personalized Web sites must also consider the more subjective user-centered perspective, and the literature is considerably sparser in this regard. User satisfaction is only partially determined by the accuracy of the algorithmic implementation and, further, user satisfaction may not be achieved even in systems that do provide accurate information (Swearingen & Sinha, 2001). In a user-centered design approach, design decisions are based on the experimentally validated value to users of a system’s features and facilities (Vredenburg, Isensee, & Righi, 2001). Thus user-centered evaluations must involve the testing of the system by (and for) users. Some of the existing evaluation literature has suggested using an evaluator who attempts to take the role of a “typical” user of the system; but we have learned from experience (Alpert, Karat, Karat, Brodie, & Vergo, 2003; Karat, Brodie, Karat, Vergo, & Alpert, 2003)
that testing must involve actual intended users of the system because doing so may elicit results that are unexpected based solely on the system developers’ analysis, and reveals more accurately the real user’s perspective.

In the general case, usability studies for computer-based applications attempt to determine whether the software, in actual use, meets users’ requirements; whether the software performs as it should in supporting users as they attempt to accomplish specific tasks; whether typical users are successful in achieving their goals; whether users can understand and use the application (whether they comprehend what they can do and how); the rate, frequency, and severity of user errors; the rate of and time duration for task completion; and so on. The goal is to test “how well the functionality fits user needs, how well the flow through the application fits user tasks, and how well the response of the application fits user expectations” (Usability First, n.d.). Usability testing may involve such abstract issues as the appropriateness of an overall system metaphor and such low level details as the placement of widgets on the screen, the use of color, and the wording of textual content. Usability testing informs the design of interactive software by obtaining the user’s perspective regarding the design, rather than simply relying on the intuitions of the designers and implementers of the software.

Even when researchers have spoken directly to the idea of evaluating the usability of adaptive or personalized systems, they have not addressed the entire problem: Such discussions often revolve around traditional usability issues or around Boolean comparisons of a whole system with and without its entire adaptive functionality (Weibelzahl, Lippitsch, & Weber, 2002). Of course, standard usability issues must be addressed when evaluating adaptive systems: We do care whether users can accomplish their goals using the system, and further, whether they can accomplish their goals faster or more accurately using a system that adapts to their needs than when using a system that does not. And usability evaluations and system evaluations will have interdependencies: If the system’s personalization mechanisms simply do not function well, the user will lose confidence in the system and all of its personalized recommendations (McLaughlin & Herlocke, 2004). But there are other factors that must be considered, issues that go to the heart of the user experience.

As in the design of any software, developers of personalized solutions begin with what they consider to be “good ideas” regarding the sorts of adaptations that would serve users, using intuitions about users and the software’s functionality. And as in case of other interactive software, these intuitions must again be verified by contact with actual users at some time before application deployment. In the case of personalized applications, however, additional questions that go beyond traditional usability must be addressed by user-centered evaluative studies. The functionality offered by personalized applications must not only match users’ needs and, perhaps even more importantly than before, their expectations, but also their desires and level of trust in computational systems. User studies in this domain must not only assess ostensibly quantitative measures such as time-to-task completion, but qualitative issues such as users’ confidence and belief in the system’s recommendations, personalizations, and other adaptive behaviors. We must determine not only whether the system is usable for performing tasks, but also whether it is acceptable to users and enhances, rather than degrades, the user experience. In this paper, we discuss some of these issues that go beyond the purview of traditional usability evaluations.

The issues discussed in this paper are derived from user studies of personalized Web sites in a particular e-commerce context, specifically the Web site of a large computer hardware, software, and services provider (Alpert et al., 2003; Karat et al., 2003). As such, the issues themselves are derived from empirical evaluations. They may be
considered a step moving toward the full realization of the issues and factors that must be addressed in personalized Web site evaluations.

USER-CENTERED PERSONALIZATION MEASURES

As mentioned previously, there are many proposals in the adaptive systems literature aimed at evaluating whether the application or Web site in question performs its adaptations correctly or accurately. And usability studies of (nonpersonalized) Web sites have shown that ease of use can increase the number of revisits and purchases (e.g., Nielsen, 2003). We touch only gently on general usability issues here. Instead, this discussion focuses on the user’s views and opinions of personalized adaptations, not only whether they work as intended, but even if they do so, whether users want the Web site to be making and using inferences and data about the user to influence or direct an adaptive presentation to the user.

Evaluations of adaptive and personalized applications must ultimately address the question, do the adaptive features actually improve the user’s experience when using the site? (see also Chin, 2001). Designers, researchers, and developers may have many ideas for personalized functionality for a Web site that they think would provide users with some benefit. But actual users when confronted with such features may find them useless or, worse, objectionable. The intuitions of the builders of (personalized and all) interactive software must be confirmed by actual potential users of that software.

Here we introduce some of the questions and issues that must be addressed when performing user-centered evaluations of personalized Web sites. These must be addressed in addition to traditional usability concerns, which we will not discuss but that, of course, must be incorporated into the user-centered evaluation. For example, fundamental to any evaluation is whether the site (and its adaptive behaviors) supports users in accomplishing their goals. Or, even more specifically related to personalization, does the inclusion of personalized features make the user more “efficient” and decrease time-to-goal completion. These are important, and ignoring such issues would be foolish. In this paper, we only touch on these more traditional concerns but go further in discussing issues that are of a more subjective nature and relate to the overall user experience, not simply quantitative efficiency measures such as time-to-task completion.

Do Users Want the Personalized Behavior?

Beyond whether site adaptations support the user in accomplishing tasks and goals, the next question we must ask in a user-centered analysis of a personalized site is whether users actually desire the personalizations the site intends or purports to provide. For example, Alpert et al. (2003) found many users were not pleased with a site’s attempts to infer their needs, goals, or interests to thereby provide personalized interactions may be based on specious inferences. “Users say things like ‘don’t stereotype me -- just give me the options because I prefer choosing for myself rather than having the computer tell me what’s good for me’” (Nielsen, 1998).

One type of adaptive system behavior is to intervene while a user is working. The intervention might be to offer advice relating to the user’s plan for achieving particular goals; to offer just-in-time instruction related to information currently in view; to offer additional, related information or an alternative or associated product; and so on. In a user-centered view of the system, the question is, is an intervention wanted or timed correctly?
For example, “Clippy” is the assistive agent in Microsoft Office applications (who by default appears in the form of an interactive paper clip), who offers advice on how to accomplish goals while using the application. The question is, should Clippy intervene while users are working, and when? Overwhelmingly, at least anecdotally, users dislike the assistive agent and its interventions, and many users disable the advice-giving assistance. Problems here include not wishing to be interrupted while focusing on actual work. This can be considered the annoyance factor and may be based on the cognitive load of having to interrupt a plan to focus on advice for an alternative plan. Perhaps more important is the fact that the assistant often does a poor job of inferring the user’s goals and plans. Thus, not only is the interruption unwanted, but the advice is not useful anyway! Due to the extensive use of these application products, many users are wary of computer applications’ attempts to infer their needs and simply do not trust them to be smart enough to do a good job at it.

Questions Regarding the Use of Prior User Behavior for Adaptive Site Behavior

In personalized Web sites, a user may attempt to find or explicitly ask for information on a particular topic, and the site uses information explicitly provided by the user and implicitly inferred about the user to find and (perhaps adaptively) display or recommend pointers to the appropriate information. The first question this raises is, what implicit information does the site use in making personalization decisions? Where (sites, pages, topics, products, etc.) has the user browsed before? Which search hitlist items has the user clicked on before? Does the site use information about the user’s apparent current information needs, for example, current task and inferred goals; recent needs; needs some time in the past; general long-term interests; where the user navigated and the topical or product information the user viewed; or information gathered about other users? How does a personalized site adapt to individual users — that is, on what information are the system’s adaptations based?

First, personalized sites typically use information explicitly provided by users about themselves, in either questionnaires or in the course of performing actual tasks (e.g., the user’s mail zip code is obtained when the user makes a purchase; this can later be used to provide information personalized by location, such as nearby movie theater listings). In the case of multi-user systems such as Web sites, personalized systems may also use information about other users, including their behavior on the site (e.g., for collaborative filtering, what did other users purchase?). In addition, intelligent personalized sites use implicit information gathered about the user, based on the user’s previous behavior on the site. This includes information obtained by observing the user’s previous navigations (e.g., what topics, products, genres did the user look at before?) and clickstream data (e.g., what links did the user click?).

An application-centered evaluation of such a site might ask questions about how well the system’s algorithms perform, for example, does the collaborative filtering engine accurately display the most popular related items? (McLaughlin & Herlocke, 2004). A user-centered evaluation of such an application must ask at least two questions. First, does it make sense — in the context of this site — to use prior user behavior to decide what to present to that user? And, do users want such personalized site features and have it based on their own previous performance and/or the previous behavior and decisions of other users?

Personalized content, based on implicit information, such as previous navigation paths, also met with mixed reactions in our previous studies. The notion of basing content on previous navigation was rated positively by participants overall, but some participants were so adamant in their disapproval of this feature, and their opinions were
so clear and passionately articulated, that they must be considered by developers of personalized sites. One participant stated the explicit-implicit problem succinctly: “I like to have more control and less assumptions made.” Other participants expressed skepticism that this feature could be implemented in a way that would make it generally valuable to them. Specifically, participants expressed some level of concern about a site’s ability to do this well enough to be useful. The overarching message was, “adapting content based on past navigation would be a nice thing, but we don’t believe you can do it well, so don’t do it at all.”

Clearly, using a particular user’s previous behavior is not always useful: “I viewed pages about x before, but I have very different goals and needs now; don’t bias what I can view based on what I did before.” Participants mentioned “shifting goals” as a problem that they believe would not be handled well by systems that use inferred goals to guide current and future presentations. They asserted that their needs, even on a single site, change over time, and they do not want adaptive behavior of the site to be based on their obsolete goals. As Nielsen (1998) puts it, “Having the computer personalize the website to the user assumes that the computer can guess the user’s needs. This is difficult to do and even more difficult when you consider that the same person may have different desires at different times.”

Refining this result further, adapting content based on immediate context was met with favor by our participants. For example, personalized recommendations can be based on the content of the Web page that is currently visible. It appears that using the immediate or current context to influence concurrent or immediately ensuing content is seen to be useful, whereas attempting to infer current goals based on navigation or other information from the past was not universally welcome. Overall, participants agreed that there ought to be a logical “limit” regarding how far back into one’s past history the site should look for implicit information about goals and interests, and further that this limit should be the current “session.” That is, the consensus view was that a user’s past history should have a limited life span: It is acceptable for the site to adapt content based on the user’s current task and navigation context and even the user’s context and history since he/she logged on today, but it should not look at past behavior beyond this point to a disjoint time or session in the past.

A further complicating issue relating to the implicit gathering of information about a user’s past interaction history is: Is all navigation behavior and clickstream data even relevant or meaningful, shifting goals notwithstanding? Therefore exactly when should such information not be collected by the site? Participants in our studies did not want data collected implicitly about them — and “remembered” in their profile — during exploratory sessions on a site unless they specifically authorize it. As one participant explained, “Hey, I might just be knocking around the site for a while...it doesn’t mean anything, and you’ll fill up my profile with a lot of junk if you implicitly collect that information. Wait until I know that I’m really after something before you start collecting data about what I’m doing, and let me tell you when that is.”

**Consideration of Context**

Some personalization features are based on the behavior, attitudes, likes and dislikes, navigation, or purchases of other users. For example, many existing e-commerce sites recommend additional “related” products to the user when a purchase transaction is about to be completed: “People who bought this product also bought products X, Y, and Z.” This is a simple form of collaborative filtering or recommender technologies (e.g., Burke, 1999; Resnick & Varian, 1997; Schäfer, Konstan, & Riedl, 2001). When applied in the context of e-commerce, these technologies use the buying behavior of prior customers to attempt to
“predict” which products a new customer may be interested in purchasing. But in our user studies, some participants expressed objections such as, “I am not like other people, I have different needs.” Additionally, this feature might be perceived simply as an intrusive marketing ploy: One of our participants found it to be an “obnoxious” attempt at marketing more products.

Looking a bit deeper, it appears that user attitudes about collaborative filtering may in fact be influenced by a variety of factors including the type of e-commerce site involved, the particular product being purchased, the type of user, and the reason an item is being purchased. Our previous evaluation studies involved a specific class of user, a particular type of e-commerce site, for a particular category of products and services: Users were business managers buying computer equipment for their enterprises, driven by specific business requirements in their actual jobs. What other customers purchased is not interesting or important to these users. The upshot is that our users had equivocal reactions to a feature that is nonetheless in extensive use: Collaborative filtering is clearly viewed by users as a benefit in other e-commerce settings, such as book and music sellers like Amazon.com. The clear conclusion is that individual personalization strategies, such as recommender systems, are not necessarily effective or beneficial across the spectrum of users and activities. Instead, user opinions and desires regarding such technologies may depend on multiple dimensions of the e-commerce scenario in question, such as the type of product being purchased, whether the purchase is for one’s self or for one’s company, and whether subjective parameters such as taste or genre are relevant to the item being purchased.

Confidence in and Understanding of the Site’s Personalizations

As we can already see, usability measures for personalized systems are significantly interconnected; For example, if a user does not trust that the site is capable of making reasonable inferences regarding his/her current goals, the he/she will not want the site’s (perhaps specious) adaptations. From the user’s perspective, then, an important question is, do users believe computer systems can do the proposed adaptations well (enough to be useful)? Are users confident that a site can perform the personalized adaptation without annoying them or wasting their time? As we have noted, in our previous studies we found that the confidence issue is so important that some participants disclosed that they do not want any information that has been collected implicitly by the site to become a part of their persistent personal profile. Instead, they wanted only information explicitly provided by them to be remembered by the site: “I want the stored information to be based on what I told you, not what you think I’ve said.”

Especially if the site is making decisions regarding the customizing of information shown to individual users, are users confident the site is giving them “good” or the “best” information available? “When the user knows that a screen has been adapted to them, it is natural for them to wonder just what has been adapted to them. What might a different user see? Are they missing out on something?” (Kay, 2001). These thoughts may intensify a user’s lack of confidence in an individually customized site. In a survey of Web users, 94% said that being able to trust the information on a site is very important or somewhat important to them as they decide to (re)visit a Web site (80% said very important; 80% also said that it is very important that the site be easy to navigate) (Consumer Reports WebWatch, 2002).

Confidence in the site also relies heavily on being able to make sense of the site and its behaviors. In a user-centered analysis of a personalized site, one ought to ask, does the user understand what is being adapted due to personalization, and why? The issue is one of determinism and comprehension. “To navigate through web-sites (e.g., presentations, online-shops, or learning
courses) the user requires a mental model of the site’s structure” (Weibelzahl & Weber, 2001, p. 74). It may be difficult to form a coherent model of the structure, content, and behavior of a site when these change over time and circumstance (although Weibelzahl & Weber argue that an adaptive site may require building a less complex mental model than a nonadaptive site). A site may be more difficult to understand and learn to use when multiple instances of the same user-system interaction result in different behavior by the system. Does the user understand what is changing and why it is changing? These are questions that must be addressed in a user-centered evaluation of a personalized site. Does the user understand why the site is “adapting” its behavior and output? Is the system predictable: “Will the user know, with a reasonable degree of certainty, what will happen when (s)he takes an action?” (D’Hertefelt, 2000). Can the user understand how the site behaves and is he/she disconcerted by the fact that the content shown in a specific context is not always the same? Is the user experience degraded because the ability of the user to understand and predict what the site will do is diminished? Paramythis, Totter, and Stephanidis (2001) refer to this issue as transparency. Users want to readily be able to make sense of site behavior, to understand a site’s rationale for displaying particular content. When past behavior or other nonobvious implicit information is used to generate content, the users’ confused reaction — “Where did this come from?” — conveys to users the notion that they are not in control. On the other hand, content whose origin is obvious or readily inferable is met with favor, while content that is based on something the user, or other users, did at some temporally distant time is often met with disapproval.

Users seem to have similar expectations of a dialog with a software application or Web site as with other people. That is, it appears that users desire responses from a Web site to follow logical conversational conventions (Grice, 1975; Searle, 1969); for example, they expect responses to be relevant to the ongoing dialog and to be as informative as required but not more so. This result coincides with the experimental work of Reeves and Nass (1999). After conducting numerous studies, Reeves and Nass concluded that users’ expectations regarding their interactions with computers and other media are based in large part on social interactions in real life, that is, users expect computers to obey rules that come from the world of interpersonal interaction. When a site provides more information — or, in some manner, other information — than what is expected, the user may not immediately know what to make of the “extra” information. In discussing many features, we heard from our users that they want to understand, without difficulty, why and how the computer side of the ongoing bilateral conversation, represented by the content the Web site displays, chose to “say” what it has displayed.

Further, does a user’s need to understand what is happening vary with the type of personalized site? If personalized adaptation is based on, say, previous navigation, the resultant application behavior may not always be clear to the user. For example, the simple collaborative filtering mechanism implemented on the Amazon site is explained as “Customers who bought [this book] also bought…” Thus the attempt is made to have users understand this simple personalization. On the other hand, when personalized results for a particular search query result in differing output at different times, does the user understand why the results differ? During usability evaluation, we must also be sure that when a site does explain its behavior, the explanation is satisfactorily informative from the user’s perspective.

Andersen, Andersen, and Hansen (2001) assert that users of adaptive e-commerce sites wish to be surprised by the site, but in a very different manner than what is being discussed here. They mean pleasantly surprised in terms of value-added services as a reward for using the site. First, they state that users wish to see recommended products related to what they are already purchasing. We
saw in our user study that this is dependent on the e-commerce context: Users of book seller sites (as in Andersen et al.) may wish to have this feature, whereas in many other product-purchasing contexts this is not a welcome feature. Andersen et al. also state that users wish to be \textit{surprised} by special offers associated with use of the site (e.g., lower prices than in brick-and-mortar stores and flexible delivery options). On the other hand, users do not wish to be \textit{surprised} in the conventional sense; if they ask, “What color is the sky?” they do not expect a response about shoe sizes in North America.

Confidence and trust in a site of course also touch on the broader issue of privacy. The importance of this issue is brought into relief by a survey in which Web users were asked to rate their confidence in various types of organizations and enterprises (businesses, newspapers, banks, charities, government, etc.). Web sites rated among the lowest, and the overwhelming reason was lack of trust regarding the handling of private information (Consumer Reports WebWatch, 2002). For a given site then, usability evaluations must also determine whether users are willing to divulge information about themselves to the site. Do users of the site under evaluation believe that the value added by the site’s personalization features is worth the user-perceived risk in disclosing private information? Are they confident that the site will use the personal information in ethical ways? Is an official privacy statement — in which the site spells out a legally binding description of how it will use and disseminate (or not) personal information — necessary?

**Who is in Control?**

In our previous studies regarding personalized Web sites, the most important issue to users was their fervent desire to be — or at least feel like they are — “in control.” “The feeling of security experienced by a user of an interactive system is determined by the user’s feeling of control of the interactive system” (D’Hertefelt, 2000). The issue is one of trust, and again has interdependencies with other issues, such as confidence and comprehensibility. “An interactive system that allows the user to feel in control should in the first place be comprehensible” (D’Hertefelt, 2000). But also, does the user trust that the inferences the personalized site has made about him are correct? “People usually do not know the reasons behind some of the personal recommendations, which often results in their distrust of the personalization mechanism” (Wang & Lin, 2003). Is there a way for the user to understand the kinds of inferences the site is making? Should there be? Can the user correct the inferences and other profile information? How granular is the control — that is, is it simply on/off for all adaptation, for subsets of the adaptation features? What is the accuracy rate required for the adaptation to become a net benefit to the user? If content or features are elided as a result of inferences made about the user, can the user easily “see” what they are missing: While users may feel that at times personalization may be useful, they also believe the application must provide ways to view the “full,” nonpersonalized or nonadapted content or information (Nielsen, 1998). Can the user view, and even modify, his/her personalization profile? These are the sorts of questions that must be addressed in a user-centered evaluation of a personalized Web site.

In our studies, this control issue emerged most strikingly in terms of being in control of one’s profile, the persistently stored personal information collected by the site about the user. As noted previously with regard to confidence and trust in a site, users ask, “What are you going to do with this data; can I trust you to maintain ‘intimate’ information about me?” While this result is certainly no surprise, it is prevalent among all users and is a strongly emotional issue. As such, it can be considered a “deal breaker” — users will not provide personal information and will not perform transactions on a Web site that in their opinion cannot be fully trusted to use profile information.
in an ethical and private manner. Andersen et al. (2001) also discuss this issue. Users want to be able to review, modify, delete, or add personal information to their profile at any time. This should be another focus of usability evaluations of personalized Web sites, to determine how the users of the specific site feel regarding these issues and what might be done to ameliorate their concerns (for example, Kay and her colleagues have attempted to address these sorts of “feeling in control” issues in personalized systems with scrutable user models and adaptations; see, e.g., Kay, 2001; Czarkowski & Kay, 2005).

Of course, there is a delicate balance that must be maintained between adaptability of the system and the user’s sense of control: “Increasing the flexibility can also increase complexity and diminish comprehensibility” (D’Hertefelt, 2000). Thus the need for actually testing personalized sites with users is further intensified — personalized systems attempt to balance adaptability versus users’ sense of control, and usability testing must be performed to determine whether the site has succeeded in this balancing act.

**How Much Work is Involved on the Part of the User?**

Web site users are loath to spend extra time and effort to enter personal information, even to enable a site to “know” more about them for personalization purposes. Nielsen (1998) invokes the notion of the paradox of the active user to explain this user behavior and preference. When encountering a new application, users wish to immediately engage in actual tasks, tasks that further their own goals. This is especially true when visiting Web sites; users have a specific goal in mind (e.g., purchasing a CD) when they visit an e-commerce site, and have little desire to first enter into an extended session of entering information about themselves before being able to accomplish that goal. “Web users are extremely impatient and want to get something useful out of a site immediately” (Nielsen, 1998).

An alternative to lengthy data-entering sessions is a technique known as “permission marketing” (Godin, 1999), in which a user’s profile or user model is incrementally constructed over time as the user interacts with a service or product provider, such as an e-commerce site. In this scenario, customers are asked only for information sufficient to complete a specific transaction or obtain a particular service, but over time a more complete user profile is obtained. An important aspect of permission marketing is that users receive an observable and immediate benefit in return for the small amount of information explicitly provided to the site and are therefore motivated to comply.

Notably, in our e-commerce studies in which permission marketing was evaluated, users rated the feature very highly. Users also expect that information explicitly entered once will persist — that is, users do not want to be asked by the site to enter the same information at a later time for a subsequent transaction or interaction.

The clear implications for usability evaluations are to determine whether users consider the explicit entering of personal information onerous or annoying, and whether there is consensus among users regarding the implied cost-benefit relationship. Do users ultimately find benefit in the site’s personalization features in spite of the amount or level of work involved in enabling the site to personalize or adapt its interactions?

**WHAT IS THE SAME?**

The aforementioned discussion focuses on what is different about evaluations of personalized Web sites and systems, that is, what distinguishes evaluations of such sites from other Web sites. It enumerates questions and issues that must be addressed in the assessment of personalized sites.
from a user-centered perspective, including asking not only is the site usable, but does it provide functionality and affordances users actually desire, that provide obvious value to users, and that users will choose to use. The evaluation process must address these many questions posed previously. The pragmatics of evaluating these issues is where things are the same as other thorough and comprehensive user-centered assessments. The techniques and approach are the same, the focus and issues addressed are expanded.

As for other types of Web sites, user-centered evaluations of personalized sites certainly ought to involve a system prototype that users can view and perhaps minimally interact with. Upon deciding what personalized features you wish to potentially incorporate into the site, a prototype that reifies those features should be constructed. Evaluation studies should be performed early in the design process using site prototypes; this can be a money- and effort-saving technique if designers’ initial intuitions regarding adaptive features and functionality do not match users’ opinions of them. This savings may be greater in the case of adaptive functionality than traditional software because the former may involve techniques that are difficult and time consuming to implement. As Paramythis et al. (2001) suggest, “Eliciting user feedback regarding the modeling process requires that at least a prototype of the system exists.” Taking this a step further, initial user testing should begin when only a prototype exists, that is, before the site is fully implemented, so that many design and implementation decisions are made prior to the expense and time of building the full site.

A reasonable method of putting the site and its personalization behaviors in front of users without the expense of actually building the system (including its adaptive functionality, which is often complex to implement) is to use paper prototypes, a technique often used in formative usability evaluations. Here, drawings of potential screens are shown to potential users, providing a sense of what the fully implemented system would look like. The images may be skeletal wire frames of the proposed screens or fully rendered realistic images of actual Web pages. Here, drawings of potential screens are shown to potential users who may express their opinions of particular screens, including their content and affordances. Usability study experimenters may be “in control,” demonstrating the proposed site design to focus groups or individual users by walking the study participants through scenarios of interaction, an approach much like the Design Walk-through technique for usability evaluation (Vredenburg et al., 2001). Or participants may discuss what they would choose to do at the interface, what actions they would take to accomplish some scenario-based goal. Experimenters can then show the appropriate image of the site’s response to the user action — for example, a new Web page or the same page with updated information — and the evaluation process iterates over several scenarios.

Evaluations of design ideas might be also performed with prototype Web pages built using presentation software, such as Microsoft® PowerPoint®, thus using digital images on a screen rather than paper. Realistic screen shots can be created using a graphical drawing and editing tool. Taking this notion a step further, in addition to being able to show users static screen images, PowerPoint possesses the ability to easily add programmatic behaviors to provide true interactivity, without the cost of a full, “real” implementation of the actual system. Users cannot only see what screens might look like in the implemented site, but can push buttons, enter text, and in general “use” the interactive prototype, whose behaviors mimic the ultimate implementation, in hands-on, scenario-based interactions. This technique offers a prototype for user testing of greater fidelity than merely showing static screen images and gives users a truer sense of the look-and-feel of the site.
Of course, this implies that driving the evaluation should be realistic scenarios of use of the Web site. Each scenario should involve a “story” in which the user must accomplish a particular goal by using the Web site. The full corpus of scenarios must include ones that exercise the personalization features the site offers. For example, a scenario of use for a computer-purchasing site might involve the goal of purchasing a memory card that is compatible with a particular computer (Alpert et al., 2003; Karat et al., 2003).

One approach might be to contrast performing a particular scenario using two different prototype sites, with and without specific personalization features that might or might not support the user in accomplishing specific goals. Experimenters can walk users through interaction with mock-site prototypes, or users can use, hands on, a minimally interactive prototype, to accomplish this same scenario goal with the two prototypes. Or the walk-through or interaction may occur with only a single prototype, one that incorporates and demonstrates a particular personalization feature. Then, experimenter-led discussions with focus groups and with individual study participants, written and oral questionnaires, time-to-task completion, number of clicks, and keyboard interactions — those materials and procedures typically incorporated into user evaluations of interactive systems — would also be employed (as in the personalization evaluation studies reported in Alpert et al. (2003) and Karat et al. (2003).

For example, questionnaires might list features such as “The site will conduct constrained searches for accessories and upgrades, searching only among those that are compatible with the products you already own,” and study participants would be asked to rate each feature in terms of its value to the participant using a Likert scale ranging from “Highly valuable” to “Not at all valuable.” Evaluations must interrogate whether the personalization features actually helped the user accomplish his/her goals. Questionnaires might include assertions, including such general statements as, “I believe the system helped me in accomplishing my goals” and “The site did not understand very well what I wanted to do and did not offer information helpful to accomplishing my goals,” and more specific statements such as, “When I wanted to purchase memory compatible with my laptop, I found the site helped me in accomplishing my goal” and “When I wanted to purchase memory compatible with my laptop, it was helpful that the site showed only those accessories that are compatible with my particular computer model.” Assertions might also probe the affective issues that have been discussed; for instance, “I liked when the site tried to understand what I was trying to accomplish,” “I’m comfortable with the Web site trying to figure out what my goals are,” and “The site should not try to infer what I’m trying to accomplish and should let me be completely in control.” These too would require Likert ratings from “I strongly agree” to “I strongly disagree.” Group and individual discussions should be sure to focus as well on issues such as the desirability or acceptability of the site’s attempts to infer users’ needs and goals, and how well the system’s intervention indeed facilitated the success of goal achievement.

**CONCLUSION**

Design of personalization or user-adaptive systems (or any software technology) cannot occur in a vacuum, specifically, it cannot usefully proceed without assessing the value and usefulness to users of the concepts proposed and implemented by researchers and developers. Is the overall user experience enhanced due to the inclusion of personalized features and functionality?

We can see that many of the presented user-centered measures interact and overlap: User trust and confidence in a Web site will plainly be affected by the quality of the system’s inferences regarding what the user wants to see; if a user cannot understand why particular information is
being displayed, he/she will have less confidence in the site; if the user is confused by the site's actions, they will feel less in control of the user-system interaction, and so on. The measures may be evaluated with and by users as individual items or joined to form more complex evaluation issues. In either case, the evaluation of personalized Web sites must consider several features, issues, and questions, including:

- Do users desire the particular personalization adaptations provided by the site?
- Do adaptations that apparently succeed in one application context (e.g., collaborative filtering on Amazon.com) necessarily enhance the user experience in the context of the site being evaluated?
- Is the site using appropriate information for its adaptations (e.g., previous navigation, explicitly entered information, previous click-throughs, etc.)?
- Do users find the site's adaptations predictable and acceptable, or unintelligible and even unnerving?
- Are users confused by seeing information they did not explicitly request?
- Do users have confidence and trust in the site based on experiencing its personalized adaptations?
- Are users satisfied with the amount of work they must perform to allow the site to personalize user interactions?
- Do users have an adequate sense of being in control (even though the site may behave differently at different times and circumstances)?
- Are users willing to relinquish control to the extent required to allow the site to personalize interactions?

Many of the questions, issues, and measures we have raised and studied are qualitative (and at times, emotional) in nature. Assessments of personalization features will of course vary across Web site domains, user types, and individual users. Researchers, usability professionals, and developers need to have a broad sensitivity to the issues we have listed, and will be well-served by investing in appropriate user-centered studies before implementing personalization features on their Web sites.

ABSTRACT

Usability is integral to software quality. Software developers increasingly acknowledge the importance of user-centered, Web site development. The value of usability engineering and the role of the usability engineer (UE) are less understood. A common assumption is that the UE’s role is only to be a user advocate. To this role, we add the responsibility of addressing concerns of other stakeholders in Web site design and development. We discuss usability engineering and the processes that it encompasses, such as project planning, requirements definition, user-centered design (UCD) and evaluation/testing within the context of traditional software engineering lifecycles. We define the UE’s role throughout a user-centered, Web site development lifecycle. This lifecycle integrates compatible usability engineering processes into software engineering processes, drawing examples from research and experience.

INTRODUCTION

People use the Web in a variety of ways. Their interaction with the Web can be self-motivated or externally motivated; their proficiency novice or expert; their needs and expectations simple or complex. To engineer a successful and satisfactory user experience with a Web site, we need to understand issues such as why people go to
a Web site; what they expect and intend to accomplish at the site; and everything impacting on their experience.

A Web site is the result of a set of processes, usually iterative, beginning with conceptualization, planning and requirements definition, then going on to design, version production, and testing/evaluation, before culminating in the site launch. For usability engineering to be fully integrated into Web site development, its practices must be fully integrated into software development lifecycles (Addelston & O’Connell, 2004, 2005). Lifecycles are structured frameworks for software development activities. For example, Figure 1 incorporates elements that iterative lifecycles typically include. In practice, the sequence and frequency of activities can vary. Research and experience show that including usability in software engineering lifecycles is critical (Mayhew, 1992).

Developing a Web site is a team effort. Each team member has roles and responsibilities. The roles of the usability engineer (UE) are integral to these processes and to the team implementing them, primarily because the UE promotes a user-centered perspective. Software engineering of a Web site addresses a variety of purposes: building a new site; upgrading, refurbishing, maintaining or introducing new information or functionality to an existing site; and replacing a legacy site. These purposes track to the goals of the Web site providers. Software engineering is not inherently user centered. It becomes user centered by incorporating usability engineering. User-centered processes for Web site development are compatible and simultaneous with software engineering lifecycle processes.

Building usability into a Web site requires user-centered processes. Such processes require defined roles and activities, which, in turn, depend on common definitions of concepts, inputs, outputs, and tools. From the start, team members must share an understanding of users’ attributes and needs. This understanding underpins the collaboration necessary to incorporate user-centered processes into Web site development.

Figure 1. A generic, variable sequence, iterative Web site development lifecycle illustrates points where usability engineering is most beneficial

Note: With the exception of version production, each of the activities in the outer ovals includes both usability engineering and software engineering processes. In practice, the sequence and frequency of activities can vary.
Guided by Figure 1, this chapter addresses the following topics:

- Usability
- Users
- User interface
- Usability engineering
- Software engineering
- Integrating usability engineering into software engineering lifecycles
- Lifecycle activities

The chapter ends with a summary and references.

USABILITY

People outside the field of usability engineering sometimes consider usability to be obvious, but vague and unstructured — something common sense can recognize and accomplish. Sometimes they are surprised to learn that the field has its own definitions and established processes. Although those people are happy to define usability as “I know it when I see it,” for UEs, a strict definition underlies our focus on users’ needs and our goal of meeting those needs through usability engineering processes. This chapter discusses users’ needs in the context of human-computer interaction (HCI), specifically as users interact with Web sites.

The International Organization for Standardization (ISO) defines usability through the attributes of users’ interactions with software products in specific contexts of use: efficiency, effectiveness, and user satisfaction. We “boil these attributes down” to two outcomes: (1) user success and (2) user satisfaction (1998). The ISO definition implies that usable software must be accessible.

Throughout this chapter, we draw illustrations from our work in a specialized branch of usability called accessibility. Accessibility enables people with disabilities to experience success and satisfaction with software to a degree comparable to that enjoyed by people without disabilities. Although some authors treat accessibility as distinct from usability, we consider it to be a subdomain of usability in which the users are people with physical and/or cognitive disabilities (Hix & O’Connell, 2005).

USERS

In the context of this chapter, users are people who interact with Web sites. In the sense in which we use the term, users are also known as end users, the people who visit Web sites and interact with their contents. The term user excludes people employed in a Web site project, for example, the UEs. It excludes the site’s providers and others who have any stake in the Web site. People close to the project can be too technical or too expert in a domain to represent a user who does not have the same training, goals or background. Those close to the project run a high risk of unintentionally clouding their view of users’ needs with their own commitment to achieving the project’s goals.

Many variables are inherent to users (Bias & Karat, 2005). Some are intrinsic, for example, age; gender; experience with technology; intellectual or aesthetic preferences; interaction styles; and the presence or absence of physical or cognitive disabilities. Other variables, such as employer goals and working environment are extrinsic, but affect the user experience. Many user attributes can decline with age, for example, memory and perception of color contrast (O’Connell, in press).

Each user brings a cluster of capabilities and limitations to any interaction with a Web site. These are the well-documented human capabilities and limitations in perception, manual dexterity, memory, problem solving, and decision making (e.g., Baddeley, 1990; Brown & Deffenbacher, 1979; Mayer, 1992). For example, the limitations of working memory are well known: seven plus
or minus two “chunks” (sets of items), with the size of a chunk varying depending on the user’s experience (Miller, 1956). Research has found that working memory can be further limited by environmental characteristics, for example, noise, fatigue, perceived time pressure, and other sources of stress (Bradley, 1990). Correctly applying such research findings to Web site design is the UE’s responsibility.

Some user attributes are physical. The term user includes people with disabilities as well as people without disabilities. Users with physical disabilities require a Web site that accommodates those disabilities. For example, a user with low manual dexterity may be a skilled problem solver, but have difficulty clicking on small screen elements with a mouse. As content density increases on Web pages, the need for small controls rises. Consider a page with a long list of expandable or contractible menu options. By offering the expanded state as the default, the site accommodates users with low manual dexterity, relieving them of the need to click on the tiny controls. Tradeoffs are inevitable. The user who cannot expand or contract the list must contend with content density. Accommodating users’ capabilities and limitations is rarely simple. Sometimes we must accommodate several factors at once. The user with the manual dexterity disability may also have a visual disability brought about by age.

The World Wide Web Consortium (W3C) considers the needs of users with a wide variety of disabilities, the W3C gives guidelines and success criteria for assessing accessibility (W3C, 2004). For users with special needs, an accessible Web site provides perceivable content; operable content components; understandable content and controls; and content compatibility with other technologies (Caldwell, Chisholm, Slatin, & Vanderheiden, 2005).

Publishing a Web site makes it available to the world, but it is not possible to design for the world. Certainly, there are generic commonalities across Web sites. Any Web site can have hyperlinks, controls, and information architecture. But, any Web site will also have unique features to meet the needs of its targeted audience. Designers need to know the characteristics of the site’s targeted audience to promote their success and satisfaction at the site. They must also project future user characteristics. For example, the intended audience needs to include users with disabilities, even if none of the current users has a disability. Today’s able user may have a disability tomorrow. Age brings disabilities (O’Connell, in press). New employees may have disabilities.

A Web site goal is to enable its users to experience success and satisfaction by accommodating each user attribute of the set of targeted users as well as the unique constellation of attributes defining each individual user. However, the “average” user is a myth. Designers need to understand the range of each attribute within a group of users and to recognize that users will fall at all points along the range (e.g., low to high spatial ability).

To help us accommodate these ranges while still focusing on targeted users, we group users into classes, rather than design for them as individuals. We define user classes by people’s participation in a set of user attributes. For example, for a theater-ticket vending site, the senior citizen user class will include the attributes, aged 65 or over and partial memory loss. The first attribute qualifies these users for a discount; the second tells UEs that the interface needs to remind users of the time of the show. Other user classes for this site would include adults, children, and members of theater clubs, each class having its own attributes.

### User Participation in Web Site Design

It is essential to include users in the process of Web site design because users will do what they will, not necessarily what the designers or developers want or expect them to do. User behavior can be anticipated up to a point, but not predicted in exact detail. Not being intimately familiar with
The Usability Engineering Behind User-Centered Processes for Web Site Development Lifecycles

The design of a site, users will try to do what seems logical to them, even though their logic may conflict with the designer’s or developer’s logic. According to Shneiderman (1998), users do not make errors of intention because they are doing what seems logical to them in the context of the task they are trying to complete. Users do not try to get lost, but they do get lost.

User involvement in design extends our understanding of human behavior within the context of the site and its stakeholders’ goals. In some projects, users participate in focus groups and interviews or respond to surveys. They join in conceptualization and design discussions. Observing users interact with a Web site provides the most valuable new insight, taking UEs to a level of understanding not otherwise possible. These observations are combined and analyzed to develop profiles of the range of expected interactions. Observing users interacting with the site identifies unanticipated needs and behaviors. Analyzing observational data produces requirements exceeding what programming logic, technical expertise, and the best of intentions can identify.

Some software engineering processes eliminate user participation but purport to accommodate a user orientation. These include assigning a user surrogate and processing user information channeled through a nonuser, such as the user’s manager. In contrast, usability engineering relies on close interaction with real users at the strategic points where their input is most crucial. It documents input from the users who actually participated in lifecycle activities.

Knowledge gained from usability engineering cannot be gained by other means. This is not to say that users drive design. Users are not designers. It is a key role of the UE to translate the understanding of users and their needs into design recommendations. It is a key role of designers and developers to incorporate usability recommendations into interactive interfaces that promote users’ success and satisfaction.

Users’ Mental Models

Along with their capabilities and limitations, users bring with them their previous experience of computers and Web sites. We assume they have built mental models, that is, psychological representations of the ways in which computers and Web sites work (Carroll, 1990; Johnson-Laird, 1983; Van Der Veer & Del Carmen Puerta Melguizo, 2003).

Highly experienced users can have mental models of different categories of Web sites, for example, sites for entertainment, information gathering, and e-commerce. According to the user’s mental model, an entertainment site should use bright colors and animation, whereas an information site should use subdued colors and minimal animation, for example, only to demonstrate an integral concept. Abstracting and representing users’ mental models is another job for the UE. Tools for doing this include cognitive task analysis (e.g., Crandall, Kline, & Hoffman, 2006).

User expectations for Web sites are based on their experience with the Internet. They have expectations for the behavior of controls, for example, the back and forward button, Tab key, and Enter key. They have expectations for hyperlinks, for example, a link once activated will change its color. Some expect to be told whether clicking on a link will take them outside the site. Sometimes, users worry about whether they will be able to get back to where they are if they click on a link because they have been unable to form a definite mental model for link behavior. This uncertainty can arise when they have experienced links behaving inconsistently across sites.

USER INTERFACE

In one sense, a user interface (UI) is software that people use to interact with technology. For UEs it is a matter of layers. Above the underlying
technology is the important look-and-feel layer (Garrett, 2002). Feel refers to more than the point and click paradigm; it also refers to what users hear, for example, a sound associated with an alarm. The UI includes both the user’s actual and expected mode of interaction with a Web site, for example, keyboard, mouse, or speech. Whether the designers intend it or not, because of mental models the UI includes implied functionality based on similarities to familiar software. In the broadest sense, the UI is the virtual place where the user’s mental model, meets the designers’ system model (Bolt, 1984). Aligning these models is a goal of usability engineering (Norman & Draper, 1986).

**USABILITY ENGINEERING**

Usability engineering is a set of defined, user-centered processes, grounded in research and experience-based principles. The purpose of usability engineering in Web development is to raise the potential for users’ success and satisfaction and, thereby, to support Web site providers’ goals. The UE must understand the complex set of variables residing in any user group and apply this understanding to promote users’ success and satisfaction. This understanding is what makes usability engineering critical to achieving Web site usability. Because people’s styles of interacting with technology change as technology progresses, usability engineering is a continually evolving field informed by applied research in human interaction with technology.

The UE applies expertise not usually found in other software development team members to make an essential contribution to the quality of a Web site. As noted by Bias and Karat, “good usability is not standard for most Web sites…” (2005, p. 2). When usability engineering is not part of Web site development, the team faces a high risk that, at the least, the site will not promote users’ success and satisfaction; at worst, it will inhibit users’ success and satisfaction and thereby prevent achievement of the site providers’ goals. This outcome would be a disservice to the providers and other stakeholders.

Usability engineering is practiced by UEs who typically have training and experience in a variety of disciplines. In the case of Web work, relevant experience is in fields such as psychology, HCI, testing protocols, and design. The UEs’ work is distinguished by its orientation toward the user, but usability engineering is more than user advocacy. For example, in addition to understanding users’ mental models and expectations, the UE must also be well versed in technology, standards, and laws. To create feasible design approaches, the UE must understand organizational and project goals. To integrate usability into the lifecycle, the UE must be able to communicate with users, stakeholders, and other members of the Web site development team.

A Web site has several objectives. While delivering information and functionality, it also bears the responsibilities of putting the site providers’ best foot forward and achieving their business goals. A Web site’s usability influences users’ impressions of the site providers’ integrity and trustworthiness. UEs are qualified to coordinate the factors necessary to meet the needs of both users and site providers. As we show later, the means to this end is to incorporate usability throughout a software development lifecycle.

**Usability Engineering Principles**

Usability engineering is a multi-disciplinary field. With roots in human factors, it also draws on disciplines such as software engineering, linguistics, biology, cognitive psychology, technology, and graphic design. These fields’ diverse contributions are documented in usability principles, a set of research and experience-based, widely accepted guidelines for achieving usability (e.g., Koyani et al., 2003; Mayhew, 1992; Shneiderman & Plaisant, 2004). UEs continually update usability principles
Usability principles empower design strategies to meet users’ needs and expectations, while avoiding unnecessary, inappropriate features that burden schedules and budgets.

Most usability principles trace to human capabilities and limitations. A user with color deficiencies can detect changes in brightness or shape but cannot distinguish between certain colors. Therefore one usability principle tells us never to rely on color to convey meaning. An important usability principle requires taking steps to assure users always feel in control. Progress bars and hourglasses give users a sense of where they are in a process, contributing to their sense of control. Another principle obliges UEs to direct users through design, for example, leading them through a Web-based form, by following their expectations, for example, whether the family name should precede or follow the last name.

Stakeholders

Everyone who has any interest in a Web site is a stakeholder, whether they are company officers, the marketing team, or the system administrators in charge of maintaining the site. Site providers are the stakeholders who finance the Web site and set the business goals. They stipulate the purpose of the site from the business point of view. They allocate resources and set policy.

Although some consider UEs to be principally user advocates, UEs have another equally important job. That is to address the concerns of stakeholders during software development. It is the UE’s responsibility to make sure that the design, while promoting users’ success and satisfaction, also promotes the aims of the Web site’s stakeholders.

Sometimes stakeholders have misconceptions about the worth of usability engineering or how it integrates with software engineering. Recognizing and addressing this fact is an essential task for UEs; they must remedy these misconceptions or expect little chance of successfully integrating usability engineering in a Web development project (Hix & O’Connell, 2005). For example, it is not uncommon for stakeholders to mistakenly consider usability engineering an expensive add-on that puts users’ needs above all others. To counter this misconception, the UE will give examples of usability as a cost-effective and cost-justifiable, integral contributor to achieving the site providers’ goals while instilling usability (e.g., Mayhew & Tremaine, 2005; Web Accessibility Initiative, n.d.). Another means to overcoming stakeholder misconceptions is to bring them in to watch early usability evaluation sessions where they see users encountering usability problems. When they return for later sessions after changes have been made to the UI, stakeholders observe users experiencing the benefits of designing for usability.

SOFTWARE ENGINEERING

Software engineering is the “application of a systematic, disciplined, quantifiable approach to the development, operation, and maintenance of software” (IEEE, 1990, p. 70). A software engineer plays two roles, computer scientist and project manager. On a large Web project, software engineers typically oversee both the technical and management aspects of development. They accomplish this by following lifecycles that stipulate, for example, a project’s phases, methods, activities, inputs, outputs, milestones, documentation, and risk mitigation strategies.

The software engineering view of usability has not always coincided with the UE’s definition or outlook. Historically, software engineering’s attention to usability was largely confined to summative testing activities (Hix & Hartson, 1993), validation at project’s end that people can use a Web site. Now, software engineers more often consider usability a valuable part of Web site development lifecycles.
INTEGRATING USABILITY ENGINEERING INTO SOFTWARE ENGINEERING LIFECYCLES

Software engineering lifecycles are hospitable to usability engineering. Commonalities between software engineering and usability engineering facilitate this compatibility. The two professions share tools such as use cases, although they sometimes employ them differently. They have the common goal of delivering quality Web sites, on time and on budget, to satisfied users, customers, and other stakeholders. They share terminology, but sometimes with different meanings or connotations. For example, in software engineering, the word *interface* primarily means a connection between two components of a software system, whereas, to a UE, *interface* first and foremost denotes the human-computer interface.

Software engineering and usability engineering processes can occur in parallel because their activities and outputs are compatible. Sometimes these processes are rigid, but the constraints of developing Web sites in real time against tight schedules and tighter budgets drive a trend toward adaptability. This trend emphasizes the need for a UE. In this fast-paced environment, users on the development team can be few and their involvement infrequent. In such a case, a UE draws on knowledge of the field, for example, usability principles and knowledge of users, to aid in the development of usable Web sites.

LIFECYCLE ACTIVITIES

Usability engineering has corresponding activities for most software engineering activities. Not all lifecycles incorporate the same activities. Activity sequence and frequency can vary. Some activities can be simultaneous. Each activity has goals, inputs, processes, and products.

In Figure 1, we present a high-level view of a user-centered software engineering lifecycle.

We use a generic lifecycle where all activities are connected to each other, feeding output into subsequent activities. The sequence of activities is adaptable. Within each activity, usability engineering and software engineering processes occur simultaneously.

Table 1 sets out some activities and processes of software development lifecycles. In addition to usability in general, the goal or objective of these activities and processes is to provide accessibility for people with disabilities. This table is not comprehensive, but it demonstrates how some usability engineering processes can be integrated into a software development lifecycle.

Although we maintain the importance of usability engineering throughout Web site development (e.g., Murphy, Marquis, Nichols, Kennedy, & Mingay, 2001), our discussion zooms in on the most critical iterative process areas. These core activities are project planning, requirements definition, design, and evaluation/testing. Although these are a subset of all possible software engineering activities, we designate these activities as core because they represent the “make it or break it” points in a typical software engineering lifecycle where usability engineering must be addressed. However, none of these activities stands alone. So, we place them within the context of other typical iterative lifecycle activities such as product conceptualization and version production.

Project Planning

A Web site project starts as an idea. This can be a new idea encapsulating the site providers’ vision. More often, at the end of a lifecycle, a team returns to product conceptualization when they evaluate an existing site and begin to plan future versions. In either case, the team needs a blueprint for the steps between the original concept and the insertion of the final product into the workplace. This blueprint is called the project plan.

Formal software engineering lifecycles start with project planning. Successful project planning

depends on a clear understanding by all team members of the site providers’ vision as well as an appreciation of the concerns of other stakeholders. Usability engineering and user involvement must be addressed from the start in the plan’s schedule and budget. If not, they are excluded early, with little chance of later inclusion. This is true whether development focuses on a new site or an existing site.

Project planning aims to ensure on-time, on-budget delivery of a Web site that meets its providers’ organizational goals and fulfills requirements. Usability engineering adds the goals of users’ success and satisfaction. Another primary goal is to gain site provider and team acceptance of usability engineering (Hix & O’Connell, 2005). Input to project planning includes output from product conceptualization such as market analyses and everything learned while maintaining a legacy site.

Typical processes involved in project planning are setting schedules; identifying and allocating resources; and stipulating activities, inputs, outputs, and milestones. Usually, planning is the responsibility of software engineers and managers. However, the UE contributes to planning by identifying the points where usability engineering is necessary and identifying the inputs and outputs needed to proceed from one step to the next. For example, the UE will point out the need to design and produce an accessible version with alt tags (alternative text). An alt tag is HTML code associating words with Web site graphics to describe their content. Alt tags must be present before evaluation with a screen reader, an assistive device that reads aloud the contents of Web pages, including alt tags. Screen reader users include people with little or no eyesight. Assistive hardware, such as a screen magnifier, or software devices, such as screen readers, help people with visual disabilities interact with technology. The UE also alerts the team to the need to schedule users with visual disabilities to participate as evaluators.

The product of these processes is a project plan that integrates usability engineering activities with other scheduled project activities and defines all players’ roles, responsibilities, milestones, inputs, and outputs. The unique goals of usability engineering during planning are that the Web site’s design will consider the user and be hospitable to user-centered processes, and that the project will fund, schedule, and provide usability engineering. If these goals are to be achieved, the plan must require usability engineering.

**Requirements Definition**

From the software engineering perspective, requirements definition is a set of processes that identify and document a Web site’s goals in terms of how the site will fulfill its providers’ vision by delivering information and/or functionality. It focuses on user needs assessment. Usability engineering also looks at the site from the users’ perspectives as well to verify that the users’ needs and expectations are being met. It addresses user requirements.

Web sites have functional, system performance, and usability requirements. Functional requirements define what a Web site is supposed to do. For example, a functional requirement for an e-commerce site that sells printers stipulates that the site must display photos of the printers. System performance is a measure of how well the Web site does what it is supposed to do. In our example, a system performance requirement stipulates that the site will deliver a specified photo over a 56K modem in less than two seconds. Usability requirements are sometimes called non-functional requirements. This term is misleading, however, because it diminishes the importance of usability.

Usability is a measure of users’ success and satisfaction with their experience at the site. But usability must also address the goals of the site’s providers. For example, the providers of an e-commerce site benefit from having customers
revisit their site frequently. To achieve this goal, usability requirements stipulate that a user be able to purchase a product, making no more than one error, and give a satisfaction rating of seven on a scale where nine is the maximum positive rating. Users’ success and satisfaction benefit both the users and the site’s providers.

Some interface requirements are yes/no, for example, the Web site will provide anchor links on every page at its top two levels. Others are quantified, for example, users will be able to navigate, with only one click, from a product description page to a page where they can order the product.

Some requirements are standards-driven. Standards can be defined by the site provider, for example, an in-house standard for displaying the company logo. Standards can come from groups such as the ISO, which, for example, gives standards for representing names of languages in its ISO 639 (ISO, 2002).

Sometimes requirements are legally mandated. Take the case of “special needs”, a term that refers to the needs of users with disabilities. The UI of a U.S. federal government site must comply with Section 508 of the Rehabilitation Act of 1973 as amended in 1998. These requirements aim to provide users who have special needs a quality of information accessibility comparable to that of users without disabilities.

The primary goal of requirements definition for the UE is setting usability requirements, the Web site’s obligations to address users’ needs. In usability engineering, users’ needs and Web site requirements are often the same thing.

Ideally, filling requirements will meet users’ needs. However, a Web site can fulfill all functional and system performance requirements, yet still not be usable. In the end, it is the users’ experiences of a Web site that determine whether the site has achieved the site providers’ vision. So, usability engineering promotes a perspective that incorporates the product concept, but expands it with an understanding of targeted users and their needs. Usability engineering brings an understanding of factors that may otherwise not come into the mix, for example, users’ mental models in the context of their capabilities and limitations.

Usability engineering processes during requirements definition start by considering users and their needs within the context of the Web site’s intended purposes. Inputs to this process are the providers’ goals for the site as well as existing information about targeted users and their needs. As other team members set performance and system function requirements, UEs learn whether proposed content will meet not only providers’ goals, but also users’ needs. If the provider’s goal is to inform users about weather conditions, are users people who need to know only tomorrow’s temperature and precipitation forecast, or do they include fishermen interested in tides as well? If the project involves an existing site, UEs address what worked and what did not work for its current users. This understanding empowers UEs to leverage the fact that each user’s experience of the site is a reflection of that user’s needs and expectations.

Requirements definition brings the UE face-to-face with targeted users during interviews, focus groups, and observations in their workplaces, that is, any place where people interact with the Web. The UE develops surveys and studies existing documentation such as usage statistics for a legacy site. However, existing documentation often omits the users’ real-world practices. Therefore, close interaction with users is key. However, the Web introduces the requirement of designing for a wider range of users than a project can usually involve. This factor dictates that the UE rely also on usability principles and knowledge of human capabilities and limitations within the context of Web use. The UE consults resources, such as Web sites on Web usage statistics, to keep abreast of changing interaction behaviors (e.g., Internet World Stats Market Research, 2005; Refsnes Data, 2005). Such resources inform production concep-
tualization as well as requirements definition.

The UE aims for user-informed requirements, but not necessarily user-driven requirements. Although users’ input is integral and respected, the UE must also draw on knowledge of usability engineering to inform recommendations for requirements. For example, when information must be stressed, users may have a preference for many colors and other emphasis techniques on the same display. The UE knows that a user-driven requirement for large blocks of text in upper case, presented in a large variety of strongly contrasting colors will result in adverse effects on user performance (e.g., Koyani et al., 2003). The usability-engineered requirement will specify what portion of the text to emphasize and how to emphasize it in a way that promotes users’ success. For example, the requirement will stipulate initial capitals and no more than three or four compatible colors that can be distinguished by most users with visual color deficiencies.

Once the UE has collected data on users, data analysis occurs. The first step is to define user profiles, descriptions of the Web site’s target population. User profiles record user attributes such as computer literacy; experience in the subject matter and functionality of the site; physical and cognitive capabilities and limitations; special needs; education; mental models; interaction styles; goals at the site; and tasks — all important factors that impact on user interaction with the site. In another process, user class analysis (also called user group analysis), the UE allocates user profiles into groups according to shared attributes, thereby defining user types, such as patients or policy holders.

In behavioral and cognitive task analysis (also called process analysis), the UE develops descriptions of users’ goals and the tasks they perform to accomplish those goals. These definitions are developed within the context of the site providers’ intended purposes for the site. During this key requirements definition activity, the UE studies existing documents and observes users to learn the steps and sequences that they take to accomplish goals. Behavioral analysis documents observable tasks such as receiving information and inputting to the computer. Cognitive task analysis documents users’ mental transformations and decisions. Doing mental arithmetic is an example of a mental transformation. Do users have to keep a running total in mind of their bill on an e-commerce site or does the Web site do it for them? When comparing products as the basis for decision making, is the product information displayed in a way that facilitates comparison, or does the user have to navigate between pages to find comparative data?

Task analyses include steps and work flows. They describe the users’ experience from beginning to end. For example, when users must fill out a form on a secure Web site, the UE documents the experience by identifying the initial steps users need to go through, such as receiving an information package in the mail, locating the URL for the site, locating the user’s unique identifying number for login, all long before the user navigates to the form (Gordon & Gill, 1997; Hackos & Redish, 1998; Kirwan & Ainsworth, 1992; Redish & Wixon, 2003; Schraagen, Chipman, & Shalin, 2000; Vicente, 1999).

During requirements analyses, the UE can develop personas, imaginary representatives of highly specified classes of users (e.g., Head, 2003; Pruitt & Grudin, 2003). Personas reflect what has been learned about users during requirements analysis. They are detailed descriptions of typical users, often given names and illustrated with commercial photographs. Personas become almost real to the team, serving as reminders of typical users’ needs.

The UE tracks the findings of these processes to the site’s intended content to assure that it is presented in a manner that empowers users to achieve their goals at the site. For example, during user class definition, the UE specifies groups of people with disabilities, associating needed assistive devices with the user group. The UE
introduces requirements for the site to present content in a way that makes it accessible via these devices.

In translating user needs into requirements, the UE draws on a variety of sources. The site’s goals are viewed through the lens of users’ needs. For example, consider a case where one of the site’s goals is to enhance the organization’s image by showing its chief technology officer talking about a new technical approach. Considering users with hearing impairments and users with low bandwidths that rule out multimedia, the UE introduces two usability requirements: (1) captions and (2) a text version of the presentation. Meeting these requirements benefits the organization by spreading the message to some who would not otherwise be able to receive it. Thus, the UE addresses the needs of both the users and the organization that provides the Web site.

Usability requirements become goals for later usability evaluation. Setting specific, measurable usability goals with the client provides a quantitative basis for assessing the design against users’ needs (Whiteside, Bennett, & Holtzblatt, 1990).

Although requirements definition produces helpful artifacts such as user profiles, user classes, user task descriptions, and personas, the most important products of requirements definition are the usability requirements that specify the site’s look and feel. Usability requirements become a checklist for everything that must be accomplished to promote successful and satisfactory users’ experiences at the site.

A project benefits from understanding users, the motives behind their actions, and the rationales behind their opinions about the site. When no requirements reflect users and their needs, a project is at high risk of developing an inappropriate site — a site that does not meet its intended users’ needs and expectations. It risks wasting time and resources meeting inappropriate goals. It risks negative impacts on schedule and budget because of the need to retrofit, that is, redesign and recode the UI to correct usability problems.

Although requirements are established at the beginning of a project, they are iteratively reviewed and updated as more is learned about users and the ways that the Web site’s look, feel, functioning, and performance impact users’ success and satisfaction.

**Design**

Incorporating users’ input from requirements definition, the UE participates in developing the site’s information architecture. Information architecture is like a road map; it sets out the paths that users follow to their destinations on a Web site. It is at the heart of design. Impacting more than site navigation, the information architecture impacts a page’s content and layout. The UE’s role is to assure that the information architecture facilitates navigation and makes finding information natural for users.

Important UCD processes, collectively called interaction design, consider the ways that real users attempt to accomplish goals at a Web site. UEs base interaction design on all that they have learned about the users, for example, their age-based capabilities, mental models, and expectations within the context of the goals of the site’s providers. Usability principles provide UEs with rules of thumb that inform UCD decisions. Consider a site intended for senior citizens who expect a prominent link to articles about leisure activities for seniors. The UE considers usability principles on legibility for older users with decreased visual acuity. These principles recommend a large font and a strong contrast between the font and background colors (e.g., Czaja & Lee, 2003).

**User-Centered Design**

Best practices in usability engineering include UCD, a set of usability engineering processes that focus on understanding users, their goals, their strengths and limitations, their work processes — all user attributes that impact how users will
interact with a Web site. The goal of UCD is to achieve users' success and satisfaction by incorporating the users’ perspective into design.

The UE’s multi-disciplinary background adds value to interface design. For example, understanding technology is a prerequisite for designing an accessible Web site. Publishing a Web site is simple nowadays. Adding unneeded features is tempting, just because it is so easy to do. The UE knows how to manage the impact of features, such as animations, on users with disabilities. It is a simple matter to give an information site a bright red background with flashing blue bold titles. The UE understands the biological impacts of such an approach, the potential for the eye to become fatigued because it is unable to focus (Travis, 1991). The UE also knows that animations increase download time and, that therefore, on an informational site, animations can reduce users’ satisfaction.

The UE brings to UCD an understanding of disciplines such as psychology and semiotics, the science of signs and symbols. When incorporating icons into a UI design, for example, it is important to use standard icons to mean what they usually mean and to test any new designs for user comprehension. If a standard icon is used to mean something different from what the users expect, it is likely to cause confusion. Many users will have no idea how to interpret an ambiguous icon in the context of their tasks. With effort, users can learn arbitrary meanings for icons, but they easily forget arbitrary meanings. Icons need text labels to clearly indicate the actions that will occur when they are activated (Horton, 1994).

The UE applies usability principles to participatory design, a UCD process in which users comment on design concepts and perhaps generate their own sketches. Users offer opinions on mock-ups or prototypes. A prototype Web site is like a preview of coming attractions at the cinema. It includes a sampling, but not all of the features and functions of the planned site. Sometimes it is an experiment to investigate UI concepts.

A typical participatory design process is card sorting, where users sort terms that are going to be used in the Web site into groups which they name. The UE combines results from all participants through a statistical technique. Applying usability principles, the UE then derives a meaningful organization of topics for the Web site to inform the information architecture.

We distinguish between user-centered design and inappropriate user-driven design where users’ input translates directly into design directives. Although user-driven design has the admirable quality of being user-focused, it excludes the input of a UE. In turning users’ requests into design decisions without looking at them in light of usability principles, practitioners of user-driven design run a high risk of producing Web sites that, in the end, do not meet users’ needs. Another pitfall of user-driven design is requirements creep that extends schedules and strains budgets as users add inappropriate features and functions that, at worse, will have a negative impact on their experience at the site (Andre & Wickens, 1995).

Ideally, a team of designers, developers, and UEs document UCD decisions in a style guide to promote consistent design. For example, a style guide specifies conventions for screen layout; size, spacing, and location rules for screen elements; and fonts, icons, and color palettes. The style guide evolves, continually updated to record new design decisions.

Design is rarely a one-time effort. Design versions are iteratively evaluated and revised throughout the lifecycle. In many lifecycles, design and version production are interspersed or even simultaneous. In these situations, the UE performs design consultations and evaluates iterative products, informing design decisions with knowledge of users and usability principles. UCD results in a plan for the ways that users will interact with the Web site. The principal product of design is not necessarily a ready-to-publish Web site. It can be a prototype.
Traditionally, during design, the UE has been a user advocate who consults on decisions involving the UI. In this fast-paced age, UEs are more and more involved in design creation and version production, using Web site creation tools.

Although design iterations occur throughout the lifecycle, once part of the site is implemented, programmers are naturally reluctant to make changes. Engineering usability up front reduces the need to request changes after programming. This is why UEs and programmers need to work closely together during UC design.

The principal benefit of having a UE in the loop is that design is more likely to speak to users’ needs. Results include increased productivity, shorter learning times, longer and repeated visits, increased profits, and decreased costs (e.g., Bias & Mayhew, 2005; Kalin, 1999; Mayhew 1999).

Use Cases

A use case is a formal description of ways a product can be used. It consists of a statement of goals with a description of the users and the processes the designers expect them to perform to achieve those goals. Sometimes, a use case is expressed in a sketch. Use cases first come into play in task analysis activities during requirements definition. They are referred to during design.

Use cases provide an example of how a UE can prevent a well-intentioned practice from misrepresenting users. Use cases are the product of a process analysis technique to develop a simple, high-level statement of users’ goals and processes. Use cases are common to the tool kits of both software engineers and usability engineers.

Basing Web design on use cases has strengths and weaknesses. For each module of a system, common processes are written up with the prerequisites for each process, the steps to take for the users and the system, and the changes that will be true after the process is completed. Use cases help to ensure that frequent processes are supported by the system, that they are relatively straightforward, and that the system architecture reflects the process structure.

Use cases, however, do not account for all possible user interactions at the Web site. Use cases tend to stress behavioral tasks, but do not capture cognitive tasks. Use cases do not leave room for users’ unexpected actions at the Web site. Users will naturally do what seems apparent to them, based on the cues given by the UI. A use case does not necessarily represent a natural action for users in the context of the moment. Use cases can put users in the position of having to provide unexpected input to the computer—input that the computer needs but that users do not necessarily know they are supposed to provide.

Use cases make assumptions about the users, for example, that they understand the internal logic of the system the way developers do. Consider novice users who try to use the back button only to discover it does not work because a second browser instance has launched unannounced and without taking focus. The use case depicts users navigating between browser instances, but does not accommodate their expectation to use the back button or the fact that they do not know about the second browser.

The limitations of use cases demonstrate the need for usability engineering. If design relies on use cases but omits a use case for a certain goal/process set, the site will lack important functionality or information. Conversely, use cases not derived from understanding users can result in unnecessary features or information. The UE adds value to use cases by making user-centered recommendations that would not be in the picture otherwise. The UE adds the human dimension to an otherwise limited view of the user as the provider of input to the computer and the recipient of output from the computer. The UE knows that factors such as the user’s thought processes and physical abilities are key to system success.

As with any other tool, use cases must evolve as a project progresses. During updates, the UE introduces the user perspective, incorporating...
The Usability Engineering Behind User-Centered Processes for Web Site Development Lifecycles

what has been learned since the last iteration about how users will interact with the site. Without a UE, the project risks misapplying use cases. For example, avoiding a one-to-one relationship between use case and screen, the UE assures that screens accommodate users’ decision-making strategies and work flows, not someone else’s model of discrete interactions.

Evaluation/Testing

Verification and validation (V&V) are software engineering terms for testing. Verification is iterative testing against requirements. Validation is the final testing against requirements at the end of the lifecycle. Usability evaluation is a set of V&V processes that occurs in conjunction with other V&V activities and is an integral component of an overall V&V approach. In addition to checking for conformance to usability requirements, usability evaluation has the added goal of assessing a wide range of users’ experiences at the site. The UE keeps the door open for new requirements based on the way real users interact with the site. New requirements become input to the next cycle. At project’s end, they become input for new product conceptualization.

Key user-centered, usability evaluation processes entail observing users interacting with a Web site. Activities for formal user observation include writing a test plan; identifying participant users; working with site providers to set usability goals for each user group and task; defining tasks; writing statements of goals that never tell users how to achieve those goals; preparing a user satisfaction survey; preparing ancillary materials such as consent forms; carrying out the observations; analyzing data, and writing a report (Lazar, Murphy, & O’Connell, 2004). These formal processes entail structuring evaluation activities to reflect the tasks identified during requirements definition.

Evaluation draws on the products of all earlier activities. For example, usability goals are based on input from task analysis (Whiteside et al., 1990). Designers also identify features or functions about which they have usability concerns. The UE makes sure that these concerns are addressed in the scenarios to generate information needed to inform UCD decisions.

During a usability evaluation session, users work with scenarios, sometimes behind one-way glass. On the other side of the glass, UEs often employ click-capture software; record numbers and types of user errors; document latency periods when users pause for a significant period of time trying to figure out what to do next; and record critical incidents where users must stop work because of difficulties with the Web site. Ideally, the providers, developers, and stakeholders observe users as they try to accomplish tasks at the site. Observing users interacting with the site can show them the need for changes. Nothing speaks louder about the quality of a Web site than the experiences of its users.

Using a method called think aloud, the UE encourages users to talk about their expectations and reactions while they work with the Web site. The output is metric data on users’ success accompanied by anecdotal data, the users’ own comments on what they were doing and why and what they think of the site. UEs are specially trained to put users at ease during observations and to facilitate the users’ evaluation experience, without telling users how to accomplish their tasks.

After usability observations, users often complete satisfaction surveys on their experience with the Web site. In an effort to foster reliability, the UE only collects and processes feedback on those elements of the site that the user has experienced. These surveys typically collect ratings on a numerical scale to produce metric data. They also offer opportunities for users to elaborate on their experiences.

The UE never relies solely on satisfaction data, but uses it to inform analysis of performance data collected during user interactions with the Web site. Users often report higher levels of
The Usability Engineering Behind User-Centered Processes for Web Site Development Lifecycles

satisfaction than would be expected from their observed performance. This is one reason why UEs interview users about their experience at the end of the session. Another reason is to give users opportunities to bring up points that no one else has anticipated. It is common for developers and other stakeholders to talk with users at this point, too.

Formal usability observations can take place wherever users interact with the Web site. With increasing personal computer sales and the proliferation of mobile devices, people are viewing the same sites from different locations: a conventional office, a crowded cyber café, or a subway train. Each location impacts the user experience differently. A conventional office can have lights that glare on the screen, ringing phones, and frequent interruptions from colleagues. The cyber café can have background noise and poor lighting. The subway can cause breaks in connectivity and the need to view only small chunks of information on a small mobile phone screen. Because of this, when possible, UEs try to hold observations in environments where the site will be used. Otherwise, when possible, they simulate the work environment within the evaluation environment to produce more valid findings.

It is unusual to hold formal usability observations at every development iteration. Indeed, some projects find even one or two rounds of user observations to be cost prohibitive. However, other simple, less expensive processes incorporate users’ perspectives. In an expert review, one or more UEs independently assess an interface against their understanding of users; usability principles; and applicable laws and standards. If more than one UE has performed the expert review, the UEs then meet to discuss and prioritize their findings before discussing them with the rest of the team. Another kind of expert review employs automated accessibility tools, for example, InSight/InFocus (SSB Technologies, 2004). Such tools inspect the Web site code for the UI for conformance with accessibility regulations. They identify violations and recommend remedies.

A lifecycle typically includes several V&V iterations. The product of usability evaluation is a set of recommendations to improve the potential for users’ success and satisfaction with the UI. The principal benefit is an understanding of how users interact with the site (Dumas & Redish, 1999). A unique benefit of usability engineering is the coordination of these recommendations with other stakeholder, organizational, and project goals.

Without a UE, the team risks relying on processes that appear to be usability evaluation, but actually fall short of delivering user-centered products. Examples of pseudo-usability engineering include having stakeholders other than real users provide feedback on interacting with the Web site. Another example is simply asking users to say what they like and dislike. The Web is rife with misinformation about usability engineering. Someone other than a UE trying to engineer usability based on such misinformation can arrive at invalid recommendations that fail to improve the user experience and, at worst, can degrade it. Nothing takes the place of actual success and satisfaction data collected from representative users and interpreted by trained usability engineers.

SUMMARY

We maintain that usability engineering is rigorous, process-based, and addresses needs of stakeholders, such as site providers, as well as users. We have set out a typical software engineering process and discussed key usability engineering contributions. We have demonstrated simultaneous, complementary activities whose products benefit later activities without adversely affecting schedules. We have shown what would be lacking without usability engineering and how the potential of users’ success and satisfaction increases with usability engineering. We stress
that usability engineering is the means to providing successful and satisfactory experiences for Web site users while fulfilling the goals of the site’s providers. The UE’s contribution is integral to Web site development.

Chapter 1.16

Personalization Systems and Their Deployment as Web Site Interface Design Decisions

Nanda Kumar
Baruch College, The City University of New York, USA

ABSTRACT

This chapter reviews the different types of personalization systems commonly employed by Web sites and argues that their deployment as Web site interface design decisions may have as big an impact as the personalization systems themselves. To accomplish this, this chapter makes a case for treating Human-Computer Interaction (HCI) issues seriously. It also argues that Web site interface design decisions made by organizations, such as the type and level of personalization employed by a Web site, have a direct impact on the communication capability of that Web site. This chapter also explores the impact of the deployment of personalization systems on users’ loyalty towards the Web site, thus underscoring the practical relevance of these design decisions.

INTRODUCTION

Organizations, in anticipation of the emergence of Web interface as a major point of contact between companies and customers, are beginning to employ a wide variety of technologies to build meaningful relationships with their customers. While Web interface may not be the only point of contact that customers use, organizations are aware of the advantages of using the Web to cater to the needs of the customers. This concept of “self-service” not only reduces costs for the company in the long run, but also increases customer satisfaction by addressing the transactional and the relational needs of the customer. In this chapter, I review the different types of personalization systems commonly employed by Web sites and argue that their deployment as Web site interface design decisions may have as big an impact as the personalization systems themselves. To accom-
plish this, I make a case for treating HCI issues seriously and argue that Web site interface design decisions made by organizations, such as the type and level of personalization employed by a Web site, has a direct impact on the communication capability of that Web site. I also focus on the practical relevance of these Web site design decisions by examining their effect on users’ loyalty towards the Web site.

**BACKGROUND: PERSONALIZATION SYSTEMS**

Most of the technologies and tools that companies use to manage their relationship with their customers usually fall under the banner of Customer Relationship Management (CRM) System. Even though personalization is just one piece of the CRM pie, it is a very crucial piece as effective personalization significantly enhances the ability of the organization to initiate a discourse with its customers to the point where any and all of these dialogues are seamlessly integrated with the database’s historical and transactional information. Based on the data stored in these databases and recent history (the pages customers viewed in the last session), Web sites automatically attempt to improve their organization and presentation of content. These Web sites, armed with a host of appropriate tools — including intelligent agents, recommendation engines and the like — attempt to anticipate the context of the interaction with their customers and personalize each customer’s shopping experience (Andre & Rist, 2002; Billsus, Brunk, Evans, Gladish, & Pazzani, 2002).

Personalization is a process of providing special treatment to a repeat visitor to a Web site by providing relevant information and services based on the visitor’s interests and the context of the interaction (Chiu, 2000; Cingil, Dogac, & Azgin, 2000). Personalization is needed to successfully manage customer relationships, promote the right product the customer is interested in, and

   - Three Filtering Techniques: Simple, Content Based and Collaborative Filtering
   - Business Rules

3. **Dynamic Assembly and Display of Content as Web Page**
manage content. Most of the advanced personalization might require sophisticated data mining techniques and the ability to display dynamic content without seriously compromising system resources (dynamic display of content will usually mean increased download time).

There are a few well-known techniques for personalization. Rules-based personalization modifies the content of a page based on specific set of business rules. Cross-selling is a classic example of this type of personalization. The key limitation of this technique is that these rules must be specified in advance. Personalization that uses simple filtering techniques determines the content that would be displayed based on predefined groups or classes of visitors and is very similar to personalization based on rules-based techniques. Personalization based on content-based filtering analyzes the “contents of the objects to form a representation of the visitor’s interest” (Chiu, 2000). This would work well for products with a set of key attributes. For example, a Web site can identify the key attributes of movies (VHS, DVD) such as drama, humor, violence, etc., and can recommend movies to its visitors based on similar content. Personalization based on collaborative filtering offers recommendations to a user based on the preferences of like-minded peers. To determine the set of users who have similar tastes, this method collects users’ opinion on a set of products using either explicit or implicit ratings (Chiu, 2000). Please see Figure 1 for an illustration of how a Web site could use all three personalization methods to best serve the customer.

DEPLOYMENT OF PERSONALIZATION SYSTEMS

Profiling

An intelligent way to make the Web site adaptive is to use not only the information provided by the user (such as rating the music and log-in information), but also information that could be collected based on the click-stream trail left behind by the user. These two different sources of collecting information about the consumer are known as explicit and implicit profiling. As the name implies, explicit profiling collects information about a user by directly asking him or her information about himself or herself and product likes and dislikes. This information is collected over a period of time and is stored in the customer database as a profile. Typically, the user would need to log-in in order for the Web site to access the profile and provide personalized content. Even though cookies can be used to store this information on a user’s hard disk, companies prefer to use the log-in approach as this allows the Web site to identify the unique visitor (cookies won’t help if the computer is shared within a family or if the customer accesses the Web site from a different location — say from the office).

Implicit profiling typically tracks the actual behavior of the customer while browsing the Web site. This method of collecting information is transparent to the user. While less intrusive, this method of collecting information has implications for the user’s privacy. Typically, information is collected about the pages the consumer visited, the products he or she looked at and the time that the user spent on these pages. If a (brick and mortar) company has good information systems, the data from explicit and implicit profiling can be merged with the off-line customer information (see legacy user data in Figure 1) to effectively present a seamless Web interface to the customer.

Ideally, a company should use all sources of information it has about the customer. However, when a user visits a shopping Web site (even a repeat user), it would be unsound business practice to expect the user to log-in every time to access personalized content. Hence, a good Web site would use implicit profiling and make a few assumptions about the likes and dislikes of the customer to provide adaptive content to the
customer. For example, if a customer visits a specific product page, it is a good idea to assume that the customer is interested in that particular product and provide content personalized to that user's need. Of course, in most cases, even if the user logs in, the Web site may have little else other than previous purchase history if the user has not provided any specific information on the products he or she likes.

**Personalization as an Interactive Dialogue Between a Web Site and Its Users**

The level and extent of personalization offered by the Web site will have an effect on the communication characteristics of the media. This research argues that different levels of support provided for personalization will specifically impact on the adaptiveness [similar to contingency used by (Burgoon et al., 2000)] of the Web site. This is best illustrated by discussing a real life example using Amazon.com. Appendices 1 to 3 include three screen shots that show the different ways Amazon.com attempts to personalize the experience of the customer. When the user enters the Web site, he or she is invited to log in if desired. Once the user logs in, Appendix 1 shows the Web page that is dynamically created by Amazon.com. This page recommends products to the user based on past purchase history and on the explicit ratings provided by the user to a set of select items. Appendix 2 shows the product page for a book the user is interested in. The column on the left hand side of this page shows the associated related content about the product that is displayed on this page. Appendix 3 shows the page tailor-made for the user based on his recent browsing history and past purchase history. Of course, the scenario described above assumes that the user logged into the Web site at the outset. An intelligent Web site can still adapt its content in its product page by assuming that the user is interested in the product he or she is browsing. Accordingly, the product page shown in screen shot 2 can be personalized even without an explicit log-in by the user.

If the same user were to shop for the book that he is interested in a physical store, he might have approached the sales clerk (or even a friend he had taken along for the shopping trip) for help locating the product. Now, when he mentions to his friend that he is interested in this specific book, music or movie, then it is possible to imagine a conversation happening along the lines discussed above. Of course, the above discourse with the Web site is limited by the need for a shared context. The conversation will not be totally indeterminable in terms of context and content and may not move along in any arbitrary direction as is possible in a conversation with a friend. But, this research argues that there are enough cues in the discourse initiated by the personalization system of Amazon.com that is enough to give the user the impression that the conversation is contingent within that shared context.

**Virtual Communities as Personalized Communities**

To enhance the relationship with the customers, companies can also provide support for virtual communities, as this will facilitate access to free-flowing and unstructured information beyond what is provided by the computer agents (Jones, 1997; Preece, 2001, 2002). For example, companies can aggregate the opinions of consumers on a particular product and present them to a new user who is browsing that product page. Depending on the level of support provided by the Web site, the new user can also get in touch with another consumer he or she might identify with, as is the case with Amazon.com. A recent study (Brown, Tilton, & Woodside, 2002) shows that community features create value for a shopping Web site. Their study showed that community
users accounted for about one-third of the visitors to the e-tailing sites surveyed and that they also generated two-thirds of the sales (2000 transactions worth one million dollars). Practitioners have long argued that having a vibrant community in the form consumer reviews is crucial for the success of e-commerce Web sites such as Amazon.com and Ebay.com (Brown et al., 2002; Kirkpatrick, 2002). Hence providing support for consumer reviews facilitates formation of one type of virtual community and integrating high level of support (user rating and information about the user) for consumer reviews on the product page increases personalization afforded by Web sites as these are relevant comments and opinions by different users presented on the product page.

Deployment of Personalization as Web Site Design Decisions

Reeves, Nass and their colleagues at the Center for the Study of Language and Information at Stanford have shown that even experienced users tend to respond to computers as social entities (Nass, Lombard, Henriksen, & Steur, 1995; Nass, Moon, Fogg, Reeves, & Dryer, 1995; Nass & Steur, 1994). These studies indicate that computer users follow social rules concerning gender stereotypes and politeness, and that these social responses are to the computer as a social entity and not to the programmer. When explicitly asked by the researchers, most users consistently said that social responses to computers were illogical and inappropriate. Yet, under appropriate manipulation, they responded to the computer as though it were a social entity. This, in fact, is the essence of the Theory of Social Response (Moon, 2000; Reeves et al., 1997). Thus I argue that there is value in conceptualizing the Web site as a social actor and that the Web site can be equated to the “agents” mentioned above in terms of source orientation. There are several points-of-contact between a Web site and its users that will result in responses by the users not unlike the way they would respond to a social interaction.

In the light of the above discussions, Web sites should also view deployment of personalization systems as important Web site design decisions that will facilitate or hinder this interactive dialogue between a Web site and its users. In a recent study conducted by this author, the personalization systems deployed by four major Web sites (Amazon.com, BarnesandNoble.com, CDNow.com and Chapters.ca) were compared along with the Web sites’ support for virtual communities. The results of the study showed strong support showing that level of support for personalization systems had an impact on customer loyalty. The results also suggested that Web sites should pay close attention to the way they deploy these personalization systems. Specifically, the results showed that by implementing consumer review support on the product page (as done by Amazon.com), we could simulate support for personalization systems in the absence of personalization systems.

CONCLUSION

In practice, it is advantageous for the Web sites to offer some form of support for personalization or virtual community as this makes the Web site to be perceived as more adaptive. This will facilitate better communication between the Web site and the shoppers, thus leading to higher levels of customer loyalty. Companies do understand that in practical terms it takes a lot more money and effort to acquire a new customer than to keep an existing customer and arguments presented in this chapter throws new light on the role of support for personalization and consumer reviews in increasing customer loyalty.

Good personalization systems can be very expensive to set up. Enabling an e-commerce Web site with the necessary tools to build a vibrant community costs little (especially when compared
to personalization systems), as the community members provide the content. The results of the study offer evidence that Web sites by providing support for consumer reviews could reap the benefits in terms of increased adaptiveness despite offering very little personalization. However, the ways and means of implementing support for personalization and virtual communities deserve further research. Future research should examine the implementation of these features in finer detail. This will help the organizations understand more in depth the trade-offs involved in providing different types and levels of personalization and virtual communities.

INTRODUCTION

Traditionally, programming code that is used to construct software user interfaces has been intertwined with the code used to construct the logic of that application’s processing operations (e.g., the business logic involved in transferring funds in a banking application). This tight coupling of user-interface code with processing code has meant that there is a static link between the result of logic operations (e.g., a number produced as the result of an addition operation) and the physical form chosen to present the result of the operation to the user (e.g., how the resulting number is displayed on the screen). This static linkage is, however, not found in instances of natural human-to-human communication.

Humans naturally separate the content and meaning that is to be communicated from how it is to be physically expressed. This creates the ability to choose dynamically the most appropriate encoding system for expressing the content and meaning in the form most suitable for a given situation. This concept of interchangeable physical output can be recreated in software through the use of contemporary design techniques and implementation styles, resulting in interfaces that improve accessibility and usability for the user.

BACKGROUND

This section accordingly reviews certain theories of communication from different disciplines and how they relate to separating the meaning being communicated from the physical form used to convey the meaning.
Claude Shannon (1948), a prominent researcher in the field of communication theory during the 20th century, put forward the idea that meaning is not transmitted in its raw form, but encoded prior to transmission. Although Shannon was primarily working in the field of communication systems and networks such as those used in telephony, his theory has been adopted by those working in the field of human communications. Shannon proposed a five-stage model describing a communication system. Beginning with the first stage of this model, the sender of the communication creates some content and its intended meaning. In the second stage, this content is then encoded into a physical form by the sender and, in the third stage, transmitted to the receiver. Once the communication has been received by the receiver from the sender, it is then at its fourth stage, whereby it is decoded by the receiver. At the fifth and final stage, the content and meaning communicated by the sender become available to the receiver.

An example of how Shannon's (1948) model can be applied to human communication is speech-based communication between two parties. First, the sender of the communication develops some thoughts he or she wishes to transmit to the intended receiver of the communication. Following on from the thought-generation process, the thoughts are then encoded into sound by the vocal cords, and further encoded into a particular language and ontology (i.e., a set of mappings between words and meaning) according to the sender's background. This sound is subsequently transmitted through the air, reaching the receiver's ears where it is decoded by the receiver's auditory system and brain, resulting in the thoughts of the sender finally being available to the receiver.

This split between meaning, its encoding, and the physical transmission of the meaning is recognised in psychology. Psychology considers that there are three stages to receiving data: (a) the receiving of sensory stimuli by a person, (b) the perception of these stimuli into groups and patterns, and (c) the cognitive processing of the meaning with the data (Bruno, 2002). Thus, for example, a receiver may see a shape with four sides (the data) and associate the name square (the meaning) with it. There is accordingly a split between the input a person receives and the meaning he or she cognitively associates with that input.

Consider, for example, the words on this page as an example of the psychological process through which meaning is transmitted. The first stage of the process is where the reader receives sensory stimuli in the form of black and white dots transmitted to the eyes using light waves of varying wavelength. Upon the stimuli reaching the reader, the brain will perceptually group the different dots contained within the received stimuli into shapes and, ultimately, the reader will cognitively associate the names of letters with these shapes and extract the meaning conveyed by the words.

Semiotics, which is the study of signs and their meanings (French, Polovina, Vile, & Park, 2003; Liu, Clarke, Anderson, Stamper, & Abou-Zeid, 2002), also indicates a split between meaning and its physical presentation. Within semiotics, the way something is presented, known as a sign, is considered to be separate from the meaning it conveys. Accordingly, in semiotics there are three main categories of signs: icons, indexes, and symbols. This delineation is, however, not mutually exclusive as a particular sign may contain elements of all categories. Vile and Polovina (2000) define an icon as representative of the physical object it is meant to represent; a symbol as being a set of stimuli, that by agreed convention, have a specific meaning; and indexes as having a direct link to a cause, for example, the change of a mouse pointer from an arrow shape to an hourglass to reflect the busy state of a system.

This classification of the physical representation according to its relationship with the content and meaning it conveys provides further opportunities to distinguish content and meaning...
from its physical presentation, and to classify the different elements of presentation. For example, a shop selling shoes may have a sign outside with a picture of a shoe on it. The image of the shoe is the sign, or the physical presence of the meaning, which in this case is an icon, while the fact that it is a shoe shop is the intended meaning. Equally, this could be represented using the words *shoe shop* as the physical sign, in this case a symbol of the English language, while the meaning is again that of a shoe shop.

This split of content and meaning from its physical presentation, which occurs naturally in human communication, allows for the same content and meaning to be encoded in a variety of different forms and encoding methods. For example, the meaning of “no dogs allowed” can be encoded in a variety of visual images. For instance, there might be (a) an image of a dog with a cross through it, (b) the words “no dogs allowed,” (c) an auditory sequence of sounds forming the words “no dogs allowed,” or (d) the use of tactile alphabets such as Braille, which is used to encode printed writing into a form for the blind. However the content and meaning is conveyed, it remains the same regardless of how it is physically presented.

SOFTWARE ARCHITECTURES FOR CONTENT SEPARATION

For the true separation of presentation from content to occur therefore in software, the content (namely the data or information itself as well as the application’s operations, i.e., its business logic as indicated earlier) is stored in a neutral format. This neutrality is achieved when the content is untainted by presentation considerations. This allows any given content to be translated and displayed in any desired presentation format (e.g., through an HTML [hypertext markup language] Web browser such as Microsoft’s Internet Explorer, as an Adobe Acrobat PDF [Portable Document Format], as an e-book, on a mobile phone, on a personal digital assistant [PDA], or indeed on any other device not mentioned or yet to be invented). The theories of detaching content and meaning from its physical presentation thus give a framework to separate content from presentation. Once that conceptual separation can be made, or at least continually realisable ways toward it are achieved, then this approach can actually be deployed in the design and implementation of computer systems.

There are a number of methods offered by contemporary software languages and architectures to achieve this detachment between the content and meaning, and how the content can thus be displayed. In the sphere of Web development, the extensible markup language (XML) is one such example. XML provides a useful vehicle for separating presentation from content (Quin, 2004a). Essentially, unlike HTML in which the tags are hard coded (e.g., *Head*, *Body*, *H1*, *P*, and so forth), XML allows designers or developers to define their own tags particular to their domain (e.g., *Name*, *Address*, *Account-number*, *Transactions*, *Debits*, *Credits*, and so forth in, say, a banking scenario). How this content is presented has, of course, to be defined by the designer or developer; he or she can no longer rely on the browser to format it by simply recognising the hard-coded HTML tags. The extensible stylesheet language (XSL) is the vehicle to achieve this (Quin, 2004b). Equally, the scaleable vector graphics (SVG) format, based on XML, is another World Wide Web format capable of separating content and meaning from presentation. SVG specifies drawing objects, their dimensions, colour, and so forth, but leaves the determination of presentation modality to the client viewer application (Ferraiolo, Jun, & Jackson, 2003).

Within enterprise systems, this separation can be achieved through the use of object-orientated and *n*-tier design methodologies. Object orientation works through its embodiment of the four goals of software engineering (Booch, 1990; Meyer, 1988; Polovina & Strang, 2004). These
four goals of software engineering, namely (a) abstraction, (b) cohesion, (c) loose coupling, and (d) modularity, determine the principled design of each object that makes up the system. They seek to ensure that the object only performs the functions specific to its role, for example, to display a piece of information or to perform a calculation. Accordingly, these goals seek to ensure that presentation objects only present the information, while logic objects only perform calculations and other business-logic operations. These content objects thus do not concern themselves with how the information is presented to the user; instead these content objects communicate their information via presentation objects to perform this function.

In addition to embodying the four goals of software engineering, object orientation builds on these by providing three further principles: (a) encapsulation, (b) inheritance, and (c) polymorphism (Booch, 1990; Meyer, 1988; Polovina & Strang, 2004). Inheritance allows an object to inherit the characteristics and behaviours of another object. Utilising this feature, it is possible to extend the functionality of an object to include new functionality, which may be new buttons or other interface elements within a user interface. Polymorphism is used to select an object based on its ability to meet a given set of criteria when multiple objects perform similar functions. For example, there may be two objects responsible for displaying the same interface element; both display the same content and meaning, but using different languages. In this scenario, the concept of polymorphism can be used to select the one appropriate for the language native to the user. Thus, object-orientated design can be used to naturally compliment the process of separating content and meaning from its method of presentation.

A common practice within the field of software engineering is to base software designs on common, predefined architectures, referred to as patterns. One pattern, which lends itself well to the separation of content and meaning from its method of presentation, is the n-tier architecture. The n-tier architecture separates the objects used to create the design for a piece of software into layers (Fowler, 2003). The objects contained within each layer perform a specific group of functions, such as data storage. In the three-tier architecture, for example, one layer is responsible for handling the software’s input and output with the user, another handles its business-logic processes, and the final layer handles the persistent storage of information between sessions of the software being executed. Through the use of an n-tier architecture and the separation of the different areas of an application’s design that it creates, it is possible to separate the content from its mode of presentation within software design.

Software engineering’s ability to separate content and meaning from its physical presentation can be aided by some contemporary implementation methods. These methods are based on component architectures that aim to create reusable segments of code that can be executed. This enhances object orientation, which seeks to create reusable segments of software at the source-code level. While there is not much difference in the design, having reusable segments of executable code translates to faster time to change segments, further enhancing the plug-and-play nature of software. Microsoft’s Component Object Model (COM) is a client-side Windows-based component architecture (Microsoft Corporation, 1998). This architecture enables programs to be built as individual components that are linked together using a client application to form a complete software program. This approach to software implementation provides the ability to construct similar pieces of software using the same components, where the functionality is common between the pieces of software. For example, if the storage and logic elements of a piece of software were to remain the same but the user interface were to be changed due to the differing needs of user groups, the same components forming the storage and logic sections could be used for all versions of
Communication + Dynamic Interface = Better User Experience

the software. Furthermore, this could occur while different user components were created to provide the different user interfaces required. This method would reduce the time taken to build and deploy the software amongst a group of diverse users.

Another implementation technique, built around distributed components located on different physical machines, are Web services (MacDonald, 2004). Instead of the components used to build the software being located on the same machine, different components can be placed on different machines. This results in users being able to share and access the same physical instance of objects. This enhances COM, which although it gives access to the same components, forces each user to use different instances of them.

One advantage of Web services is that they allow the existence of different user interfaces while letting users access the same physical objects used for the logic and storage processes. This type of deployment will ensure that all users are accessing the same data through the same logic processes, but allows the flexibility for each user or user group to use an interface that is the most optimal for their needs, be they task- or device-dependant needs.

THE HUMAN-COMPUTER INTERACTION BENEFITS

The human race rarely uses fixed associations between content or meaning and its physical representation. Instead, people encode the meaning into a form appropriate for the situation and purpose of the communication. Communication can be encoded using different ontologies such as different languages and terminology. Communication is thus able to take different physical channels (e.g., sound through the air, or writing on paper), all of which attempt to ensure that the content or meaning is communicated between the parties in the most accurate and efficient manner available for the specific characteristics of the situation. Currently, this is not the case with computer interfaces; contemporary interfaces instead tend to adopt a “one size fits all” approach for the majority of the interface.

In taking this one-size-fits-all approach, content and meaning may not be transmitted to the user in the most accurate form, if it is communicated at all. The characteristics of the situation and participants are not taken into account. This makes the interface harder to use than might be, if it can be used at all. Some users, such as those with a sensory disability or those with a different native language, may not be able to access the information as it has been encoded using an inaccessible physical form (e.g., visual stimuli are inaccessible for the blind). Or it has been encoded using a foreign language, which the user does not understand. This immediately prevents the user from accessing the content and meaning conveyed by that form of presentation.

Equally, terminology can be prohibitive to the ease of use of a user interface. The set of terms that we know the meaning for (i.e., ontology) is based on factors such as the cultural, educational, and social background of the user as well as the geographic area the user inhabits. This leads to different groups of people being familiar with different terminology from those in other groups, although there is some degree of overlap in the ontologies used by the different groups. The user is forced to learn the terminology built into the interface before they can extract the meaning that it conveys. This imposes a learning curve on the user, unless they are already familiar with the particular set of terms used. Hence, by using a one-size-fits-all user interface, some users will find it difficult or impossible to use.

By utilising the facilities offered by contemporary software-engineering practices, it is possible to avoid this one-size-fits-all approach and its inherent disadvantages in terms of human-computer interaction. By allowing the encoding scheme used to present software interfaces to change with different users, interfaces will begin
to mimic the processes used to encode content and meaning that are found in natural human-to-human communication. This change will result in interfaces that are accessible by those who could not previously access them, and will also result in greater ease of use for those who previously had to learn the terminology used within the interface, hence improving interface usability.

**FUTURE TRENDS**

One emerging trend is the use of explicit user modeling to modify the behaviour and presentation of systems based on a user’s historic use of that system (Fischer, 2001). Explicit user modeling involves tracking the preferences and activities of a user over time, and building a model representing that behaviour and associated preferences. This, coupled with the concept of presenting the content and meaning in the form most suitable for the user, holds the ability to tailor the content to a specific individual’s needs. By monitoring how a user receives different types of information over time, a historic pattern can be developed that can subsequently be used to present the content and meaning based on an individual’s actual requirements, not on a generalized set of requirements from a specific group of users.

**CONCLUSION**

Currently, by entwining the association between content and meaning and the physical form used to represent it, software user interfaces do not mimic natural human-to-human communication. Within natural communication, the content and meaning that is to be conveyed is detached from its physical form, and it is only encoded into a physical form at the time of transmission. This timing of the point at which the content and meaning are encoded is important. It gives the flexibility to encode the content and meaning in a form that is suitable for the characteristics of the situation (e.g., the channels available, the languages used by the parties, and the terminology that they know). This ensures that humans communicate with each other in what they consider to be the most appropriate and accurate manner, leading to encoding schemes from which the parties can access the content and meaning in an easy method.

This is not currently the case for software user interfaces, which use a too tightly coupled association between the content and meaning and the physical form used to encode it. By utilising contemporary Web-based or object-orientated component architectures, this problem of fixed encoding schemes can be overcome. Therefore, software user interfaces can more closely mimic natural language encoding and gain all the benefits that it brings.

**REFERENCES**

**KEY TERMS**

**Accessibility:** The measure of whether a person can perform an interaction, access information, or do anything else. It does not measure how well he or she can do it, though.

**Content:** The information, such as thoughts, ideas, and so forth, that someone wishes to communicate. Examples of content could be the ideas and concepts conveyed through this article, the fact that you must stop when a traffic light is red, and so on. Importantly, content is what is to be communicated but not how it is to be communicated.

**Encoding:** Encoding is the process by which the content and meaning that is to be communicated is transformed into a physical form suitable for communication. It involves transforming thoughts and ideas into words, images, actions, and so forth, and then further transforming the words or images into their physical form.

**Object Orientation:** A view of the world based on the notion that it is made up of objects classified by a hierarchical superclass-subclass structure under the most generic superclass (or root) known as an object. For example, a car is a (subclass of) vehicle, a vehicle is a moving object, and a moving object is an object. Hence, a car is an object as the relationship is transitive and, accordingly, a subclass must at least have the attributes and functionality of its superclass(es). Thus, if we provide a generic user-presentation object with a standard interface, then any of its subclasses will conform to that standard interface. This enables the plug and play of any desired subclass according to the user’s encoding and decoding needs.

**Physical Form:** The actual physical means by which thoughts, meaning, concepts, and so forth are conveyed. This, therefore, can take the
Communication + Dynamic Interface = Better User Experience

form of any physical format, such as the writing or displaying of words, the drawing or displaying of images, spoken utterances or other forms of sounds, the carrying out of actions (e.g., bodily gestures), and so forth.

Software Architecture: Rather like the architecture of a building, software architecture describes the principled, structural design of computer software. Contemporary software architectures are multitier (or $n$-tier) in nature. Essentially, these stem from a two-tier architecture in which user-presentation components are separated from the information-content components, hence the two overall tiers. Communication occurs through a standard interface between the tiers. This enables the easy swapping in and out of presentation components, thus enabling information to be encoded into the most appropriate physical form for a given user at any given time.

Usability: A measure of how well someone can use something. Usability, in comparison to accessibility, looks at factors such as ease of use, efficiency, effectiveness, and accuracy. It concentrates on factors of an interaction other than whether someone can perform something, access information, and so forth, which are all handled by accessibility.

ABSTRACT

In this chapter, we introduce the key ideas related to the paradigm of pervasive computing. We discuss its concepts, challenges, and current solutions by dividing it into four research areas. Such division is how we were able to understand what really is involved in pervasive computing at different levels. Our intent is to provide readers with introductory theoretical support in the selected research areas to aid them in their studies of pervasive computing. Within this context, we hope the chapter can be helpful for researchers of pervasive computing, mainly for the beginners, and for students and professors in their academic activities.

INSIDE CHAPTER

The recent advances in hardware and wireless technologies have leveraged the creation of the first experimental pervasive computing scenarios. Due to the belief that these scenarios will be an integral part of future living, research in this field is increasing at a fast pace. Therefore, theoretical and mainly practical studies are of great use as a way of supporting this belief.

Performing such studies, however, implies identifying the intricacies behind pervasive computing. Although its concept is quite simple, understanding these intricacies is a task which scatters across different research fields. Computer
networks, distributed and cognitive systems, software engineering, and user interface design are some of these fields.

Therefore, in this chapter our main objective is to identify and discuss, at an introductory level, some of these intricacies. More specifically, we define four major research areas in pervasive computing, namely pervasive networking, context awareness, pervasive systems development, and pervasive computing middleware. Based on this view, we then take the reader on a journey through the universe of pervasive computing, discussing concepts, challenges, and current solutions.

INTRODUCTION

Today, computing is facing a significant revolution. There is a clear migration from the traditional desktop-based computing to the ubiquitous era, where computing will be spread all around us and seamlessly integrated into our lives. It is this new stage of computing that researchers have named pervasive computing. We can say that it is the accomplishment of the so-called concept of calm technology (Weiser & Brown, 1995), or as Weiser (1993) has said, it “envisions computation primarily in the background where it may not even be noticed” (p. 1). Not surprisingly, these ideas require us to view computers in a totally different way, not only as something we log onto, work on, and log out of when we are finished (Saha & Mukherjee, 2003). Instead, we should see a computer as a portal to a repository of computational resources, making use of them to work on the background and fulfill tasks according to our needs and preferences.

Pervasive computing, also known as ubiquitous computing (Weiser, 1991), has been recognized as the third wave in computer science, following

Figure 1. Sales of mainframes, personal computers, and ubiquitous computing devices
the mainframe and the personal computer ages. Therefore, even if not fully conceived, pervasive computing will be the prevailing paradigm of the 21st century. Observing the graph shown in Figure 1, one can see the sales associated with ubiquitous computing devices follow a fast exponential growth. As more and more facilities, or services, will be available for users of such devices, this growth, even that in a lower rate, will be expected to continue. After all, it is not for nothing that academy and mainly industry are so confident on the pervasive computing paradigm.

Getting a ride on this new trend, the purpose of this chapter is to conduct the reader behind the scenes of pervasive computing, introducing the main concepts and challenges involved in it. The structure of the chapter is illustrated in Figure 2. We start with a first glance at pervasive computing by describing a sample scenario in order to provide the reader with the general concepts. It is presented as an overview of the technological advances that have leveraged the development of pervasive systems, as well as the challenges imposed by pervasive computing scenarios. In the Pervasive Networking section, we present two key concepts for pervasive environments, mobility and host discovery. The notion of context and its importance to pervasive computing will be outlined in the Context in Pervasive Computing section. Next, we present some methods that have been used for developing pervasive systems. More specifically, some techniques that application developers need in order to deal with the inherent characteristics of software for pervasive computing are discussed. Based on this discussion, we then outline in the Middleware for Pervasive Computing section the main features that should be presented by a pervasive computing middleware and how they can aid the development of pervasive applications. Additionally, some pervasive computing

Figure 2. Overview of the chapter
Pervasive Computing

middleware solutions are presented. We conclude the chapter by summarizing the actual state of pervasive computing research, and also discuss possible future directions.

A FIRST GLANCE AT PERVERSIVE COMPUTING

Imagine yourself porting a mobile device, like a handheld, while walking through a shopping mall. Now imagine you are very interested in having a cappuccino. You think it is a pity there is no place in this mall offering cappuccinos. Fortunately, your handheld “knows” that you like cappuccino, and it becomes aware that the shopping mall has just opened a coffee shop. And guess what? Cappuccinos are sold there. Based on this information, your mobile device notifies you about this news, and now you can have your desired cappuccino. While you are savoring it, you are reminded of that book you are interested in. Without hesitation, you take your device out and check to see if any store in the mall has such a book to offer. When the search is finished, you find out that two bookstores are selling the book you want. The search returns all the information you need, such as the price of the book in both stores, discounts, and payment options. With such information at hand, you select the offer best suited for you and request the book. From your mobile device, you provide all the information to complete the purchase. Now, all you need to do is go to the bookstore and get your brand new book.

Wonderful, is it not? Just by porting a mobile device you were able to savor a cappuccino and buy the book you wanted. And both tasks were completed in a very natural way, as if computing had been fully woven into our lives. This is a typical example of a pervasive computing scenario. First introduced by Mark Weiser in his seminal paper (Weiser, 1991), pervasive computing is part of an evolution chain consisting of distributed systems and mobile computing (Satyanarayanan, 2001). It envisions a world where computing and applications are embedded in everyday objects. Clothes, televisions, air conditionings, and cars are examples of such objects. They will be capable of seamlessly interacting with each other in order to perform tasks on behalf of the users by taking intelligent actions or making available relevant information at the right place and at the right time.

Weiser affirmed that pervasive computing can be achieved through three major technologies: cheap and low-power devices, a network infrastructure for communicating these devices, and pervasive applications. At the time this was said, hardware technology was not fully available to support pervasive computing. Wireless networking, as we have today, was neither available nor deployed in mobile devices. Consequently, pervasive applications could not be developed.

This started to change with the introduction of more powerful mobile devices, such as the current smart cellular phones and handhelds, that allowed for the development of more complex applications for such devices. Also, the embedding of wireless networking technologies, like Bluetooth (Bray & Sturman, 2000) and Wi-Fi (Reid & Seide, 2002), on mobile devices has promoted the availability of mobile applications. These technologies have permitted us to give the first steps toward the vision of pervasive computing. This has caused a rush for the first solutions in the field, and many works with this purpose have been developed. Oxygen (http://www.oxygen.lcs.mit.edu), Aura (Garlan, Siewiorek, Smailagic, & Steenkiste, 2002), Smart Space (Stanford, Garofolo, Galibert, Michel, & Laprun, 2003), Portolano (Esler, Hightower, Anderson, & Borriello, 1999), and Wings (Loureiro, Bublitz, Barbosa, Perkusich, Almeida, & Ferreira, 2006) are some examples of works related to the branch of pervasive computing.

However, a long road is still ahead. Despite the hardware advances in the last years, there are still a new set of problems associated with software systems for pervasive environments. For pervasive
computing to become a true reality, applications need to have full access to the information about the users and the environments in which they are situated. This is in a broad sense what has been named context, although many variations for the concept exist nowadays. The current lighting condition, temperature level, and the number of users around a mobile device are some examples of the information associated with the word context. The great challenge that remains within this scope is how to model context information, and mainly how to effectively exploit it. The effective use of context information is one of the key issues to achieve Weiser’s vision of invisible computing (Satyanarayanan, 2001). Still, acting on behalf of users requires pervasive systems to be ready for changes in their interests. Changes in the local and remote resources available should also be considered, as they are important for achieving such pervasiveness.

Going down to the networking level, we find that mobility and host discovery are two important features for pervasive environments. Whereas the former allows embedded applications to perform their tasks uninterruptedly; that is, even when the user is moving through different networks, host discovery permits a device to discover network hosts, and also to be discovered by them. Due to the discovery of such hosts, a device is then able to query for the information and resources they share, informing the user about the most relevant ones.

It is clear the preceding challenges need to be first well understood and solved. Only then can dependable pervasive systems emerge. Therefore, from this point on, we start delineating such challenges, as well as mentioning some of the current solutions for them. However, if any of the introductory ideas are not clear enough, the reader can refer to the literature presented in Table 1.

PERVASIVE NETWORKING

Pervasive networking is about the plumbing involved in the communication of devices in pervasive computing environments. Therefore, studies within this area range from the design and energy consumption techniques of wireless interfaces to the development of high level protocols, such as routing and transport ones. At this high level, mobility and host discovery play fundamental roles as enablers of pervasive environments. Research in these areas has considerably advanced, and as a result, some practical solutions are already available today. Therefore, in this section we present a review of the concepts associated with mobility and host discovery.

Mobility

You probably receive your mail at your residence, right? Now, consider that you are moving to a new house. Among other concerns, you would probably want to change the mailing address associated with correspondences like your credit card bill. In this case, you must notify your credit card company that you have just moved, and that consequently your mailing address has changed. Either you do this or your credit card bill will be delivered to the old address, which is not a desirable situation.

A scenario similar to the above one is basically what happens in computing environments enhanced with mobility. In other words, mobility must allow a device to change its physical location and still be capable of receiving network packages from the other hosts. Note that, by physical location, we are referring to the network a device is connected to. Therefore, moving through different networks is what requires a node to have its address changed.

Mobility is certainly a fundamental element for pervasive environments. The possibility for providing users with on the move networking enables applications to work in the background by invisibly searching for some relevant content. However, the use of mobility in computing systems inherently leads them to face a set of new and challenging problems, which can be grouped in the following way (Satyanarayanan, 1996):

- **Resource poverty of mobile computing devices:** It is a fact that mobile devices are resource-poor when compared to personal computers. Processor speed and memory/disk capacities are considerably higher in static computers than in mobile ones. Therefore, software for mobile computing need to be well designed in order to save processor usage and storage space.

- **Energy restrictions:** Static computers are plugged to some energy network, which is theoretically an unlimited source of energy. Mobile devices, on the other hand, depend on limited capacity batteries. Therefore, techniques for saving energy should be applied in mobile applications.

- **Variability of wireless links:** Wireless connectivity is still highly variable in terms of performance and reliability. Whereas some buildings provide high-bandwidth and reliable wireless connections, others may provide considerably less bandwidth and reliability. This can be even worse in an open environment, where connection may be shared by lots of users. Undoubtedly, these changes in wireless connectivity need to be addressed in pervasive computing systems by, for example, implementing some network congestion control algorithm.

- **Security of wireless connections:** Due to the broadcast nature of wireless links, they are easier to eavesdrop with than wired ones. Therefore, if security is already an important
feature of fixed networks, for wireless ones it is an even more important feature.

The Degrees of Mobility

The different degrees of mobility have a direct impact over the topology of a network. The more mobile are the network nodes, the more flexible the network needs to be. In the case of Ethernet networks, for example, nodes are too static. Therefore, only in sporadic situations is it necessary to change the network address of a node. Consequently, the network topology does not necessarily need to be flexible. In this case, protocols like DHCP (dynamic host configuration protocol) seamlessly solve the problem of delivering new network addresses to nodes. At the other extreme, a network may be populated by highly mobile nodes. Such a level of mobility allows users to move around areas that, for various reasons, have no fixed network coverage. In these situations infrastructureless networks are more appropriate. That is, nodes should be capable of establishing connections with each other whenever needed. In this case, the network would be formed opportunistically as more and more mobile devices get together.

Within this context, as Sun and Savoula (2002) have already pointed out, three modes of communication can be distinguished when it comes to the degree of mobility: nomadic, cellular, and pervasive communication. In the first case, no connection is necessary when the device is migrating from one network to another. A typical example of the nomadic communication is a user who uses a notebook for connecting to a network both at work and at home. Note that there is no need to keep network connections while the users are moving from work to their house. Only when getting home should the notebook receive a new address for accessing the network. In the cellular communication mode, the network is organized in cells, where each cell is located adjacent to a set of others. All cells have a central element, which provides connectivity for the nodes within them. Therefore, a mobile device can move through different cells and maintain a connection with their central element, becoming thus accessible even when moving. Current mobile telephony networks are an example of this kind of communication, where the base stations act as the central elements. Finally, pervasive communication can be mainly characterized by the lack of a fixed network infrastructure different from the two previous ones. Therefore, nodes should establish connections directly with each other whenever they come close enough. These features are what characterize the so-called ad hoc networks (Chlamtac, Conti, & Liu, 2003), and will be of great importance in the deployment of pervasive computing environments.

Among the current solutions for mobility, we could cite Mobile IP (Perkins, 1997), GPRS (General Packet Radio System), and Bluetooth. Basically, Mobile IP and GPRS are mobility solutions respectively for IP and mobile telephony networks. Bluetooth, on the other hand, is a standard for short-range and low-cost wireless communication in an ad hoc way. Further description concerning these technologies can be found on the Web sites listed in the Useful URLs section.

Host Discovery

Putting it simply, host discovery is about finding other hosts in the network, and also being found by them. This apparently simple concept is of great importance for pervasive computing environments, and can be found in technologies such as Bluetooth and UPnP (Universal Plug and Play). As an example of its usage, consider the acquisition of context information in decentralized environments, such as the available services. By using host discovery, a device can, for example, find the available hosts in the environment and query them for the services they provide. This
Host discovery can be performed either by using a notification-based approach or a query-based one. In the former, a host is discovered when it notifies itself to the others. This requires the host to send its advertisement through the network, so that the others can be aware of it. Such advertisements contain information such as the address, name, and description of the hosts. The advertising task can be executed a single time (e.g., when the host joins the network) or periodically (e.g., each second). The notification-based host discovery is illustrated in Figure 3(a). On the other hand, the query-based approach, illustrated in Figure 3(b), is based on sending discovery messages and waiting for their responses, which contain information about the discovered hosts. Therefore, by retrieving the information contained in these responses, a host is able to contact the discovered hosts.

**CONTEXT IN PERSVASIVE COMPUTING**

A fundamental functionality of pervasive computing applications is to present users with relevant information or services at the right place and in the right time, in a seamless way. Such information can be, for instance, a landmark for tourists to visit based on their preferences. In this process, two key inputs are involved: the needs and interests of the user and the information available both in the environment and in their devices. The former allows the applications to define what sort of information would be relevant to the user. The latter is the source from where such information will be retrieved. Let us get back to our first example, the one presented in the First Glance on Pervasive Computing section. In that case, your desire for a cappuccino and the book you wanted to buy were your needs and interests. Whereas the former could be acquired, for instance, by keep-
ing historic information of your preferences, the information about the book has been explicitly provided by you. Based on both information, the application running in the handheld was able to determine what would be considered relevant information for you. By gathering information from the environment, the application decided that the opening of a new coffee shop and the bookstores in the surrounding area were relevant enough information to present you.

**A Definition of Context**

The preceding discussion should provide at least a first impression of what context really means. In pervasive computing literature, context has been defined in a number of ways. Some researchers have defined context by categorizing the different information associated with it. Gwizdka (2000), for example, identifies two types of context: *internal* and *external*. Internal context provides information about the state of the users, such as their current emotional state. External context, on the other hand, describes the environment on which a user is immersed, for example, informing about the current noise or temperature level. In the work of Petrelli, Not, Strapparava, Stock, and Zancanaro (2000), two types of context are identified: *material* and *social*. Material context is associated with location (e.g., at home), devices (e.g., a handheld, a cellular phone) or the available infrastructure (e.g., available networks). Social context, on the other hand, encapsulates the information about the current social state of the user, for example, in a meeting or a movie theater. Another work, by Schilit and Theimer (1994), defines three categories for grouping context information: *computing context*, *user context*, and *physical context*. A refinement of these categories is presented by Chen and Kotz (2000), through the addition of a fourth category, *time context*. The information associated with each category is presented as follows.

- **Computing context**: Network bandwidth, the cost involved in communication, and available resources, such as printers, displays, and workstations.
- **User context**: People in the vicinity and the location, profile, and current social situation of the user.
- **Physical context**: Lighting and noise levels, current temperature, and traffic conditions.
- **Time context**: Time of the day, day of the week, month and season of the year.

Note that the above ideas do not really define what is context, but instead try to give it a meaning by enumerating the sort of information that could be related. The problem in defining context in this way is that it may be hard to affirm whether some information can be considered context information or not. Additionally, a more general definition of context would certainly enable a better understanding of its role in pervasive computing. Therefore, for the purposes of this chapter, we consider a context as defined by Dey (2001, p. 45).

Context is any information that can be used to characterize the situation of an entity. An entity is a person, place, or object that is considered relevant to the interaction between a user and an application, including the user and applications themselves.

**Context Aware Applications**

Considering the current context for determining the actions that can be taken is very natural for us. We commonly use information such as the place we are at and the people around us to guide our actions. When we are in a movie theater, for example, we know how bothersome it is to speak loudly, and so most of us generally do not do so. In this scope, applications that make use of this kind of information are called *context aware ap-
applications. Such applications, however, require functionalities for acquiring and interpreting the context information, and to choose and execute an action based on it. More precisely, three elements are involved throughout this process: context acquisition, context representation, and context reasoning.

Context acquisition concerns the way context information is obtained, namely sensed, derived, or explicitly provided (Mostéfaoui, Rocha, & Brézillon, 2004). Sensed context information is gathered from physical sensors, such as lighting or temperature ones. Derived context information is computed on demand, like the time of the day and the number of people around. Finally, when context information is explicitly provided, the user is responsible for providing it. An example of this acquisition can be viewed on applications which provide a form for users to fill in with their preferences (i.e., favorite kinds of books, movies, food, and entertainment).

Once acquired, context information needs to be made available to the interested applications. This implies that it must be represented in an agreed format, so that the interested applications can “understand” the information they received from the providers. As already pointed out by Held, Buchholz, and Schill (2002), the representation of the context should be structured, interchangeable, composable/decomposable, uniform, extensible, and standardized. Structuring is important for enabling applications to filter pieces of information from the context. Interchangeability is related to the possibility of applications to exchange context information with each other. Therefore, in order to provide this characteristic, a context representation must be serializable. Composition and decomposition enables to compose and decompose context information from different sources. This allows transferring only sub-parts of the information, for example, when it has been updated, to avoid sending the whole context representation. Uniformity claims that different kinds of context information (e.g., user’s profile, device profiles, resource profiles) should be represented in a similar manner in order to ease interpretation by the applications which use them. As the number of terms and variables of a context is difficult to predict, even in quite restricted domains, extensibility is also a fundamental characteristic for context information representation. Finally, as devices and applications can come from different vendors, context information must be based on standards. This would certainly improve the exchanging of context information among pervasive computing applications. Current solutions for pervasive computing represent context in different ways; for example, using key-value pairs, XML documents (Boyera & Lewis, 2005; Ryan, 1999), object-oriented models (Henricksen, Indulska, & Rakotonirainy, 2002), and ontology-based models (Chen, Finin, & Joshi, 2003; Henricksen, Livingstone, & Indulska, 2004; Masuoka, Labrou, Parsie, & Sirin, 2003).

Considering that the context information is represented in a way that applications understand, it is possible to make use of this information and perform context reasoning. Basically, context reasoning is the use of contextual information for guiding the actions an application will take. As Satyanarayanan (2001) has already pointed out, the effective use of context information is a fundamental element in pervasive computing, as a means for achieving the invisibility feature envisioned by Weiser. The context reasoning mechanism of a pervasive computing system can be as simple as if-then-else statements, or as complex as rule-based (Nishigaki, Yasumoto, Shibata, Ito, & Higashino, 2005) and case-based methods (Ma, Kim, Ma, Tang, & Zhou, 2005). An important characteristic of context reasoning systems is the ability to deal with uncertain context information. As the information acquired by sensors (i.e., sensed context information) is prone to errors, applications should consider the quality of the acquired context information when performing their reasoning tasks. To this end, different approaches have been proposed using,
for example, Bayesian networks (Gu, Pung, & Zhang, 2004a) and Fuzzy logic (Ranganathan, Muhtadi, & Campbell, 2004).

DEVELOPMENT OF PERVERSIVE COMPUTING SYSTEMS

Based on our discussion until now, it is easy to realize that the intrinsic features of pervasive computing have an impact on the way software is designed and developed. For example, adaptability, customization, and context sensitivity are some of the characteristics that are constantly associated with pervasive computing systems (Raatikainen, Christensen, & Nakajima, 2002). Different software engineering techniques have been used when dealing with them. In this way, we will now review some of these techniques, as well as how they can be applied in pervasive computing systems. More precisely, we will discuss how the component and plugin-based approaches can be used to provide such systems with adaptability and customization. In addition, we show how they can be aware of changes in the context, through the generation and notification of events.

The Component-Based Approach

Component-based software engineering addresses the development of systems as an assembly of components. More precisely, its focus is on the development of components as reusable entities, as well as on the maintenance and upgrade of systems through the customization and replacement of such components. The main advantages of this reuse and assembly-based paradigm is a more effective management of complexity, reduced time to market, increased productivity, and improved quality (Crnkovic, 2001).

In a general way, a component is a software implementation which can be executed in a logic or physical device and can be reused in several applications of the same domain (Bachman, Bass, Buhman, Dorda, Long, Robert, Seacord, & Wallnau, 2000). The well-defined interface of the component describes the services or events that implement its functionalities. Such interface enables encapsulation of the component’s functionalities, reducing the coupling among them, and also improving the flexibility of the software design.

Figure 4. Component-based architecture
Because the components must be connected to assemble the application, it is necessary software to ensure the interaction among components, managing their service and event dependencies. Generally, such entity is implemented as a software framework. To guarantee the components will behave as expected by the framework, some interfaces, called contracts, are defined (see Figure 4). These contracts, which components are forced to implement, guarantee that the development of independent components satisfies certain standards, allowing the framework to use such components without being aware of their internal implementation details (Bachman et al., 2000).

The Component-Based Approach in Pervasive Computing

Within the scope of pervasive computing, the application of the component-based approach is straightforward in the development and maintenance of software. Due to the dynamics and heterogeneity they present (e.g., different services available, several kinds of protocols, devices with different processing power, and storage capabilities), the reuse and flexibility characteristics of components are mandatory in pervasive computing software design. The combination of these features provides an efficient way for enabling an application to seamlessly adapt. This can be performed either by dynamically changing a component by an equivalent, or by assembling a new functionality to the application.

In this context, reuse is important, for example, due to the increasing number of technologies related to pervasive networking, such as Bluetooth, UPnP, Zeroconf (Guttmann, 2001), and JXTA (Gong, 2001). Since such technologies are based on standard protocols, they can be implemented as software components in order to be reused in several applications. Reuse is not only interesting for communication technologies. Components can also be implemented for many other purposes, such as audio and video streaming and context information retrieval, and yet provide the same reuse feature.

Examples of pervasive computing systems which make use of the component approach include Aura (Garlan, et al., 2002), Runes (Costa, Coulson, Mascolo, Picco, & Zachariadis, 2005), and PCom (Becker, Handte, Schiele, & Rothermel, 2004).

Plug-in-Based Architectures

Applications based on the plug-in approach are characterized by having a functional core with well-defined hooks where extensions (i.e., plug-ins) can be dynamically plugged (see Figure 5) (Mayer, Melzer, & Schweiggert, 2002). The functional core contains only the minimum set of functionalities the application needs to run. Plug-ins, on the other hand, are intended to enhance the application by adding features to it. Therefore, plug-in-based applications can be executed even when no extensions have been installed. Besides, features that are not in use can be safely removed, by plugging out the associated plug-in.

A more revolutionary view of plug-in-based architectures is to consider everything as a plug-in. In this new form of plug-in architectures, the application becomes a runtime engine for managing each plug-in’s life cycle. As a consequence, end user functionalities are entirely provided by means of plug-ins. For such kinds of application, the extension of plug-ins through other plug-ins is thus a fundamental feature (Birsan, 2005).

Plug-in-Based Architectures in Pervasive Computing

The application of the plug-in approach in pervasive computing systems provides them with the needed characteristic of customization. From minimum, but functional software, users can gradually download specific plug-ins to their daily activities, choosing the ones which best supply their needs. Take as an example an envi-
Pervasive Computing

Figure 5. General view of a plug-in-based architecture

Pervasive Computing

It is interesting to note how the pure plug-in approach fits well when applied in pervasive computing. The plug-in runtime environment, obviously equipped with other features, like context sensitivity, can be mapped to a pervasive computing infrastructure. Applications would then be viewed as plug-ins, which could be extended by other plug-ins, and so on. Therefore, plug-ins, in this case, applications, could be installed in the user’s device on demand, and be removed from it when no longer needed.

Within this scope, the fact that plug-ins can be removed without affecting its host application is also important for pervasive computing. Mobile devices are restricted concerning disk and memory capacity, and thus it would be helpful to remove non-used plug-ins in order to save some space.

Practical examples concerning the usage of the plug-in concepts in pervasive computing can be found in middlewares like Wings (Loureiro, et al., 2006), BASE (Becker, Schiele, Gubbels, & Rothermel, 2003), ReMMoC (Coulson, Grace, Blair, Duce, Cooper, & Sagar, 2005), and Plugin-ORB (dAcierno, Pietro, Coronato, & Gugliara, 2005).

Event-Based Systems

An event-based system is the one in which the communication among some of its components is performed by generating and receiving events. In this process, initially a component fires an event,
and after that, such an event will be delivered to all the components interested in it. In an event-based system, a component can assume the role of producer, consumer, or both. The producer is responsible for generating and firing events. The consumer, on the other hand, is a component which registers itself for the occurrence of a particular event, and is notified when such event occurs.

The process of event notification can be performed in two ways: through the event-based or the callback cooperation models (Fiege, Mühl, & Gärtner, 2002). In the former, a key element is the event service. Such an element is responsible for receiving an event from a producer and forwarding it to consumers. To exemplify this process, we have presented an example, which is illustrated in Figure 6. In such a figure, we have six components (A, B, C, D, E, and F), the event service, and two kinds of events (X and Z). Some components act only as producers (components A and C) whereas others only as consumers (components B, D, and F). Finally, component E acts as both a producer and a consumer. The arrows in the figure indicate the flow of event announcements and notifications within the system. In the callback model, on the other hand, the consumer subscribes directly to the provider of the event. Therefore, the provider must keep track of the consumers for each event it provides. When some component is interested in various events, it must thus subscribe to each component providing the event. The so-called Observer design pattern (Gamma, Helm, Johnson, & Vlissides, 1995) is an abstraction of the callback event cooperation model.

The Event-Based Approach in Pervasive Computing

In the context of pervasive computing, the event-oriented approach can be very helpful in the no-
tification of changes in the context. An example would be a user, located in a shopping mall, who is interested in book discounts. Applications dispersed in the environment could frequently deliver events associated with the discounts available in the mall. Through a handheld, the users could then register their interests on events associated, for example, with books discounts. As soon as one of such events is generated by some application, a centralized event service would be able to deliver the event to the user’s handheld, which in turn would notify the user. The event could then provide the user with information such as the store offering the discounts and the associated books.

Another use of events in pervasive computing is for notifying applications about the battery level of a device. In this scenario, through the callback cooperation model, an application could specify a value associated with the remaining battery (e.g., 5%) and register itself to an event which is fired every time the battery level reaches such a value. In this way, an application could be notified when the device is about to run out of energy, in order to save some critical data before the battery be completely consumed.

The event approach has been successfully used in the development of pervasive software systems. Maybe the best example we can cite is the UPnP specification. Its event mechanism, which uses the General Event Notification Architecture (GENA) (Cohen, Aggarwal, & Goland, 2000), permits the notification of changes in a device, such as the services that have been inserted or removed from it. Other examples include the Scooby (Robinson & Wakeman, 2003) and Solar (Chen & Kotz, 2002) pervasive computing middlewares.

MIDDLEWARE FOR PERVERSIVE COMPUTING

The task of building pervasive computing applications can be too tedious if performed from scratch. In other words, the developer will need to deal with low level networking protocols, the way the context is acquired and monitored, notification of changes in the context, and methods for enabling flexibility in their applications. This, of course, deviates the attention of the developers to tasks that are not the purpose of the application. Instead, they should only concentrate on the application logic, that is, the tasks the application must perform. This is where middleware for pervasive computing comes in.

By providing a high level abstraction for application developers, middlewares can considerably speed up development time and also decrease the number of errors in software implementation (Mascolo, Capra, & Emmerich, 2002). Besides abstracting low level details, an ideal middleware should also provide the developer with robustness, efficiency, and security (Aldestein, Gupta, Richard, & Schwiebert, 2005).

These are, however, characteristics that should be presented by any kind of middleware, targeted at pervasive computing or not. From the discussion we have presented until now, it is clear that pervasive computing middleware should not stop at this point. Adaptability, for example, is part of any application in pervasive environments, and consequently, pervasive computing middlewares should present it. Take as an example the RPC (remote procedure call) protocols they use for invoking remote services available in the environment. Considering the diversity of such protocols (e.g., XML-RPC, RMI, SOAP), the middleware could be faced with situations in which it does not implement the RPC protocol used by a certain service. Middlewares for pervasive computing should be capable of transparently overcoming this problem, by downloading the specific RPC protocol implementation, installing it, and finally invoking the service. Moreover, middlewares for pervasive computing should naturally support the development of flexible applications on top of it. In other words, they should provide all the necessary tools for developers to build inherently adaptable
applications. Based on our previous discussions, the component and plug-in-based approaches can be very effective, both for the middleware and the applications running over it.

Another characteristic is that pervasive computing middlewares need to provide a way for applications to retrieve information from the context, and also to be notified about changes related to it. In middlewares for traditional distributed systems this was not required, as the context on which they were executed was too static. Therefore, the sporadic changes in the context could be easily managed by the middleware, with no need to be exposed to the applications. As a result of the dynamics involved in pervasive environments, middlewares can not efficiently take decisions on behalf of applications (Mascolo et al., 2002). It is more reasonable, thus, to expose the context to applications and let them take their own actions. At this point, context representation and event notification are very useful for pervasive computing middlewares.

**Pervasive Computing Middleware Solutions**

Current solutions for pervasive computing middlewares have been focused on different aspects, such as service discovery, service composition, context sensitivity, and networking heterogeneity. These solutions range from general purposes middlewares, like Jini (Waldo, 1999) and Aura (Garlan, et al., 2002), to application domain specific ones, such as healthcare (Bardram & Christensen, 2001) and e-learning (Apostolopoulos & Kefala, 2003). Due to their importance in the development of pervasive computing applications, in this section we outline some of these solutions.

**Jini**

Jini is a middleware focused on service discovery and advertisement. Jini services are advertised in service catalogs through a Java interface. When the service catalog address is known a priori, Jini clients make requests directly to the service catalog in order to discover services. The service catalog returns a proxy for each discovered service, which is used by clients for remotely invoking it. If the service catalog address is not known, requests are performed in order to find it. As the service provider—and consequently its services—may not be available in the network, Jini implements a lease mechanism to help clients avoid finding unavailable services. Therefore, when providing a service, its provider receives a lease, which must be renewed at a specified time interval. If the lease is not renewed, the service is removed from the service catalog, and thus can no longer be found by Jini clients.

**OSGi**

The open services gateway interface (OSGi) is a specification supporting the development of Java service-based applications through the deployment of components known as bundles (Lee, Nordstedt, & Helal, 2003). A major advantage of the OSGi specification is that such bundles can be installed, uninstalled, and updated without the need to stop and restart the Java applications. In the scope of pervasive computing, this is a fundamental feature, as it enables pervasive computing systems to adapt themselves in a completely transparent way to their users.

The main idea behind OSGi is the sharing and discovery of services. In other words, bundles are able to advertise and discover services. When advertising a service, a bundle can define a set of key-value pairs, representing the service’s properties. Such properties can thus be useful for other bundles, in order to discover the services they need. These advertisement and discovery processes are both performed through a registry, managed by the OSGi implementation. In this way, it is able to keep track of all services cur-
rently advertised and being used, thus enabling a bundle to be updated even when other bundles are executing and using its services.

**RCSM**

Reconfigurable context-sensitive middleware (RCSM) (Yau, Karim, Yu, Bin, & Gupta, 2002) addresses context-awareness issues through an object-based framework. The context-independent information of an application is implemented in programming languages such as C++ and Java. The context-sensitive information is implemented as an interface, using the context-aware interface definition language (CA-IDL). This interface has a mapping of what actions should be executed according to each activated context. In this way, the application logic is isolated from the context specification.

**SOCAM**

Service-oriented context-aware middleware (SOCAM) (Gu, Pung, & Zhang, 2004b) supports the development of context-aware services where ontologies are used for representing context information. There are two types of ontologies: *high-level ontologies* describe generic concepts which are domain-independent, such as person, activity, location, and device, and *domain-specific ontologies* define concepts which concern specific domains, such as vehicle and home domains.

**Aura**

The main focus of Aura is to minimize the distraction of users by providing an environment in which adaptation is guided by the user’s context and needs. This project, developed at the Carnegie Mellon University, has been applied in the implementation of various applications, such as a wireless bandwidth advisor, a WaveLan-based people locator, an application which captures the user’s intent in order to provide task mobility among different environments. All these applications use components provided specifically by the Aura project, as well as other components, such as the service registry functionalities provided by Jini and Coda (Satyanarayanan, 2002).

**CURRENT AND FUTURE TRENDS IN PERSERIVE COMPUTING RESEARCH**

Undoubtedly, research in the pervasive computing field has considerably advanced. At the networking level, for example, wireless communication is already possible through technologies like Bluetooth, Wi-Fi, and Zigbee. Wi-Fi, although providing a data rate of up to 54 Mbps, has high energy consumption. Bluetooth and Zigbee consume considerably less energy than Wi-Fi, but provide less transmission rates, respectively of 1 Mbps and 250 Kbps at most. The tradeoff of these characteristics must then be analyzed when deploying a pervasive computing environment. Despite these advances, enhancements must still be achieved in this area. Among them, we could point out the power consumption of wireless interfaces. Are current solutions well suited for today’s appliances? Can power consumption be improved? Or better, can the relation between power consumption and transfer rate of a wireless interface be improved? Considering this variability of power consumption and transfer rate in wireless interfaces, what would be an ideal configuration for the network and the appliances (i.e., the set of wireless interfaces in the environment and the devices) to minimize power consumption and maximize the transfer of data?

Mobility and ad hoc networking protocols have also been developed, like Mobile IP, GPRS, UPnP, and Zeroconf. The mix of wireless interfaces and these protocols have already leveraged the deployment of some experimental pervasive
environments. One point to be considered in this scope is the degree of pervasiveness of such solutions. In other words, how seamless are they concerning configuration, initialization, and finalization? Do we need to start and stop them all the time? One could still think about the performance of these solutions in current mobile devices. Do they consume too much energy? If yes, how can they be improved?

When considering the context-awareness, undoubtedly some efforts have been made in specific application domains. As examples, we could cite tourist information, healthcare, sports, learning, multimedia, and intelligent houses. However, context is far from being used as it is intended. For example, some of the current solutions focus on discovering needed services, but do not well address the assembly of new functionalities based on the requirements of the users and the resources available. In this case, what sort of methods should be applied in order to improve this assembly? Is the context information represented in a reasonable way, so that it simplifies such assembly? Work in this area should involve more precise representation of the context, including the resources and the interests of the user, as well as more intelligent methods for better determining what is relevant to the users, and what is not. Determining what is relevant to the user also requires the application to be capable of capturing the user’s preferences, needs, and different states (i.e., social, emotional, physical). User preferences are mostly acquired by providing forms which users fill in. However, how boring can it be for a user to update such forms? Considering that this is a boring task, are they willing to pay this price for some degree of pervasiveness? Concerning the needs of the user, they are commonly obtained explicitly; that is, the users provide to the system what functionality they are interested in. Can this acquisition be enhanced? Is it possible to draw a profile of the user from its reoccurring needs in order to enable pro-activity? What about the information concerning the states of the user? Is it reasonable to require the users to explicitly set them in their personal devices? Can this information be acquired in a different way, through sensors placed in the user’s body for example?

Another point to be analyzed concerns the social impact pervasive computing may cause. Consider, for example, the way people will react to sensors that detect their presence and suggest actions for them. Will they be pleased for these suggestions or angry because there is always some boring gadget telling them what to do? One should consider also whether people will accept having sensors in their bodies for obtaining information like their health and emotional state. Will you? What about privacy and security? Many people are still mistrustful of checking their banking accounts through the Internet, what would they say about sharing personal information in an open environment inhabited by all kinds of people? Certainly, all these social factors are as important as technological ones, and thus, must be deeply investigated.

PERVASIVE COMPUTING FOR KNOWLEDGE AND LEARNING MANAGEMENT

As we have seen throughout this chapter, the evolution that has taken place in hardware and networking technologies, along with the dissemination of mobile devices like cellular phones, make pervasive computing the prevailing paradigm for the next computing systems. Within the scope of this trend, one of the aspects that pervasive computing can greatly contribute is knowledge management, mainly when we consider the increased demand for learning independently of time and place (Lytras, Pouloudi, & Poulymenakou, 2002). The use of information technology (IT) in the context of knowledge management is already commonplace. As already stated by Marwick (2001), many different IT solutions can be used...
Pervasive Computing

for this purpose, with the goal of enabling knowledge to be acquired, created, and disseminated by transforming it from tacit to explicit forms and vice-versa. One of the great advantages of IT, in this case, is the possibility to transpose the barriers of time and space. Based on this, it is not hard to realize how pervasive computing can aid in further transposing such barriers. With pervasive computing technology, members of an organization are able to establish meetings, anytime and anywhere, with the goal of sharing their knowledge. In this scenario, video and audio over the Internet could be used to give the impression that the members are in a real meeting. Therefore, people from organizations geographically distributed would not need to travel to meet each other. Another use of pervasive computing technology is for the generation of reports with the intent of disseminating someone’s knowledge. With the possibility of having Internet connection whenever needed, members of an organization could prepare reports about a specific topic and then distribute them to the others, no matter where they are. Within this process, any needed document, either internal or external to the organization, could also be accessed, enabling knowledge to be acquired, created, and disseminated in a ubiquitous way.

Due to this possibility of extending the limits of knowledge acquisition, creation, and dissemination, it is not surprising to see the first solutions trying to combine pervasive computing and knowledge management. An example is the work of Will, Lech, and Klein (2004), which proposes a tamagotchi-based solution for supporting mobile workers in finding relevant information for the work they perform. Basically, this solution works by enabling a mobile device to interact with information suppliers in a seamless way, through a continuous and proactive matching between the information they provide and the one needed by the mobile workers. Another work in this category is the p-learning Grid, also known as the pervasive learning Grid (Liao, Yang, & Hsu, 2005). As its name indicates, the p-Learning Grid is targeted to support mobile learners in pervasive environments. The overall idea of this work is to represent learning objects (LOs) using Grid services (Foster, Kesselman, Nick, & Tuecke, 2002), distributing them among several connected computers (i.e., Grid infrastructure). In this way, through such an infrastructure, LOs can be dynamically discovered by client devices, using, for example, the current learning needs of users. Other solutions in this field include the work of Amman, Bright, Quirchmayr, and Thomas (2003) and the GetSmart system (Marshall, Zhang, Chen, Lally, Shen, Fox, & Cassel, 2003).

CONCLUSION

In this chapter, we have discussed some concepts surrounding pervasive computing. We have provided the reader with a high level understanding of the pervasive computing paradigm at different levels, and thus we have ranged from networking to software engineering issues. By using this approach, we presented a broad vision related to pervasive computing to aid researchers, students, and professors in research and teaching activities.

Based on the concepts we have discussed, it is possible to conclude that the application of pervasive computing in the real world is still in its beginning. Many efforts have still to be made in order to bring the primary vision of pervasiveness to real life. One could ask whether such vision will really be conceived. This is, for now, a question which is still unanswered. Answering it will require deep theoretical and, mainly, practical studies. This is what researchers should focus on, and thus, this work has been an introductory theoretical contribution to this end. We believe the concepts presented here will be summed up in other works, and also be useful when developing
real world applications, with the intent of reaching a reasonable vision of pervasive computing.

APPENDIX I: INTERNET SECTION: UBIQUITOUS COMPUTING GRAND CHALLENGE

The Ubiquitous Computing Grand Challenge is a community of researchers from different parts of the world targeting ubiquitous computing (http://www-dse.doc.ic.ac.uk/Projects/UbiNet/GC). Their research is focused at different levels of ubiquitous computing, from social to technological. With this purpose, this community has been proposing a set of, as they call it, foothill projects, within the scope of ubiquitous computing. This community still provides a mailing list used by their members to discuss the projects and directions of the community, among other adjacent topics. The registration to the list is open.

Interaction

Select one of the foothill projects presented on the Ubiquitous Computing Grand Challenge Web site and prepare one of the following items:

1. A research paper with at least 3000 words, without counting images, or
2. A presentation at least 40 minutes long.

Both the paper and the presentation should present in what way the selected project contributes to the ubiquitous computing research, the state of the art, and practical applications. Remember that it could be helpful to access the mailing list, for example, to generate some interesting discussion concerning the selected foothill project.

APPENDIX II: CASE STUDY

A Usual Day with Pervasive Computing

At half past six in the morning, Jessica’s alarm clock wakes her up, as programmed. As soon as she gets off the bed, the curtains of the bedroom are automatically opened and the alarm clock stops yelling. Within one hour, she dresses for work, takes her breakfast, gets her stuff, and leaves.

When arriving at work, a camera positioned at the entrance of the parking lot recognizes Jessica and her car, and thus, the gates are automatically opened. She greets the gateman and enters. At this point, her car automatically selects the best parking options. She chooses one of them, and leaves the parking lot.

Jessica is about to enter the company when a sensor in the entry of the building detects her presence, and by knowing the elevator she usually takes to go up, warns her that it is on maintenance. Based on the number of people waiting at each elevator, it suggests the best option for Jessica.

Finally, Jessica gets to her office, and at this moment environmental conditions, like lighting or air conditioning levels or curtains opening, are automatically adjusted according to her preferences. Furthermore, a coffee machine, which knows that Jessica usually drinks a cup of coffee in the morning, greets her and asks if she would like some. She has a meeting within a few minutes, but she thinks she has enough time to taste her daily coffee. Then, through a voice command, Jessica orders the machine to prepare it. After finishing the coffee, she then leaves the room for another day of work.

Late in the night, Jessica gets ready to return home. When leaving the parking lot, her car informs her that the usual way she takes home is too congested and it automatically provides an alternative route.
On her way home, she receives a phone call on her cellular phone. As she is currently driving, the phone redirects the caller’s talk to an audio output located in the car. Jessica can use an available microphone to talk to the caller by forwarding the audio streaming to the cellular phone. Therefore, the focus on the driving is not compromised.

When she gets home, the mailbox identifies her and notifies her about the three letters left in it. She takes the correspondences and enters her home, when again the environment is adjusted according to her preferences. Furthermore, the answering machine detects her presence and automatically informs her of missed calls. Through a voice command, Jessica starts listening to each message left. She then finds a message by her mother, asking her to return the call as soon as she gets home. Jessica stops listening to the missed calls and orders the answering machine to dial her mother’s number through her cellular phone. After talking to her, Jessica has dinner and finally gets ready to sleep. She lies down on her bed, and automatically the air conditioning is turned on, the curtains are closed, and the alarm clock is set to wake her up in the morning to have one more usual day with pervasive computing.

Questions

1. What other pervasive computing features would be helpful for Jessica’s daily activities? For each feature provide a detailed description of how it would be fit into the above scenario.
2. Do you think the current society is ready for this kind of technology? Explain your answer.
3. Considering the hardware and software technologies we have today, identify/describe issues of creating the pervasive computing scenario described.

INTRODUCTION

Nowadays, we are experiencing an increasing use of mobile and embedded devices. These devices, aided by the emergence of new wireless technologies and software paradigms, among other technological conquests, are providing means to accomplish the vision of a new era in computer science. In this vision, the way we create and use computational systems changes drastically for a model where computers lose their “computer appearance.” Their sizes were reduced, cables were substituted by wireless connections, and they are becoming part of everyday objects, such as clothes, automobiles, and domestic equipments.

Initially called ubiquitous computing, this paradigm of computation is also known as pervasive computing (Weiser, 1991). It is mainly characterized by the use of portable devices that interact with other portable devices and resources from wired networks to offer personalized services to the users. While leveraging pervasive computing, these portable devices also bring new challenges to the research in this area. The major problems arise from the limitations of the devices.

At the same time that pervasive computing was attaining space within the research community, the field of grid computing (Foster, Kesselman, & Tuecke, 2001) was also gaining visibility and growing in maturity and importance. More than
just a low cost platform for high performance computing, grid computing emerges as a solution for virtualization and sharing of computational resources.

In the context of virtual organizations, both grid and pervasive computing assemble a number of features that are quite desirable for several scenarios within this field, notably the exchanging of information and computational resources among environments and organizations. The features of these technologies are enabling system designers to provide newer and enhanced kinds of services within different contexts, such as industry, marketing, commerce, education, businesses, and convenience. Furthermore, as time goes on, researchers have made attempts of extracting and incorporating the better of the two technologies, thus fostering the evolution of existing solutions and the development of new applications. On the one hand, pervasive computing researchers are essentially interested in using wired grids to hide the limitations of mobile devices. On the other hand, grid computing researchers are broadening the diversity of resources adhered to the grid by incorporating mobile devices.

This chapter presents part of our experiences in the research of both pervasive and grid computing. We start with an overview about grid and pervasive technologies. Following, there are described and discussed approaches for combining pervasive and grid computing. These approaches are presented from both perspectives of grid and pervasive computing research. Finally, in the last section, there are presented our criticisms about the approaches discussed and our hopes about the future steps for this blend of technologies.

GRID AND PERVERSIVE COMPUTING

Grid computing (in short grids) was born as a low cost alternative for high performance computing, rapidly evolving to a solution for virtualization and sharing of resources. By spreading workload across a large number of computers, users take advantage of enormous computational resources that would otherwise be prohibitively expensive to attain with supercomputers. To day, grids try to leverage a world where the access to any computational resources across sites is standardized, ubiquitous and reliable.

Grids are characterized by the use of heterogeneous and non-dedicated resources, scattered under different administrative domains and linked through low-bandwidth channels. There are no guarantees neither whether a certain resource will be available at a certain moment nor, once available, it will keep available during any interval of time. Due to these features, grids are best suited for applications that can adapt themselves to deal with intermittent resources.

More recently, grids are going towards defining a service-oriented architecture, OGSA, where resources are advertised and used as services. OGSA extends traditional service-oriented architectures by the standardization of a number of helper services, concerned with the maintenance of the whole infrastructure. Such services include load balancing, QoS assurance, redundancy of services, and so forth.

Pervasive computing is also a kind of distributed computing. The general vision is that computation is embedded in objects of everyday life, such as clothes, rooms, automobiles and domestic devices. These objects and environments collaborate on behalf of people, balancing proactivity, context information and pre-known information about users’ profiles to provide personalized services to users, on the right place and on the right moment.

Pervasive computing materializes in the form of smart spaces. These environments are characterized by collaboration between embedded devices, wired infrastructure and users. Normally, users interact with smart spaces through portable devices. These devices carry information about
the users’ profiles and may tell the environment how the user wishes to interact with it. Alternatively, the environment itself may know about users’ profiles, and query them by “sensing” users through sensors. Regardless of how the environment gets aware of users’ profiles and how it senses the presence of users, the basic principle of pervasive computing is to disappear from human perception. In other words, users should benefit from decisions made by environments without being prompted every time about what they wish the environment does for them.

THE PERVERSIVE PERSPECTIVE

Pervasive computing is mainly characterized by the use of resource constrained mobile devices. Thus, from the perspective of pervasive computing, the main research focus is on using resources of grids for supplying lacks of mobile devices.

Current approaches for bringing together grids and pervasive computing will be discussed in the following.

Using Grids for Hiding Limitations of Mobile Clients

In the perspective of pervasive computing, using grids for supplying the lack of resources of mobile devices seems to be the major contribution that grids may bring to the pervasive computing research. Grids have plenty supply of resources that are needed by mobile clients. Nevertheless, current attempts to virtualize the capacity of mobile clients (Clarke & Humphrey, 2002; Hingne, Joshi, Finin et al., 2003; Kumar & Song, 2005;) still falls into strong assumptions about the communication between mobile client and grid. Particularly, successful applications of this approach are yet restricted for those cases where the interaction between mobile client and grid requires low data exchange or where some alternative is found for supplying the system with needed data.

For instance, Kumar and Song (2005) proposed a grid-based infrastructure where mobile clients run only helper applications linked to the grid. As proof of concept, a virtual file system was developed linking some folders in the PDA’s file system to a bigger hard disk in the grid. Thus, files and full programs may be moved to the grid, staying in the PDA only those files and programs more frequently used. All content moved to the grid is consumed on demand through streams.

The approach of Kumar and Song (2005) reveals the main weaknesses of integrating pervasive and grid computing. Due to limitations of battery autonomy, portable devices should avoid using intensively their network interfaces. Therefore, a successful integration between grid and pervasive computing should consider applications where there are not large amounts of data being exchanged between portable devices and grid.

The issues of restricted data exchange between portable devices and grid are better targeted by Hingne et al. (2003). In this approach, the authors consider a niche of applications where data needed by portable clients require intensive processing over large amounts of data. However, the authors assume these data can be obtained from different fonts than users’ devices, such as sensor networks and databases, both directly linked to the grid.

In this scenario, users use portable devices to perform queries for data that need to be transferred, and eventually created, on-demand. Data can be directly gathered from data sources, as a databank or some sensor, or may need to be created from the processing of some other data. In the last case, a grid is used to process data and thus reduce the overall client waiting time.

Besides, on the one hand, the approach of Hingne et al. (2003) presents a solution for the issues discussed before, on the other hand it may be posing an economical challenge. Deploying an entire infrastructure, for example a sensor network, to substitute the mobile device role of acting as the system’s entrance of data may be prohibitively expensive. Also, this solution may
restrict user mobility in the sense that users become restricted to interact with the system only where the infrastructure was deployed.

**Using Grids as Test Bed of Pervasive Applications**

Adequate test beds are used for revealing problems very difficult to identify in traditional development environments. The development of any kind of application achieves better results when prototypes are tested and developed in situations and scenarios close to the real ones. There are many examples of well succeeded test beds for classes of applications, for example PlanetLab, which is an overlay network over the Internet intended to be a test bed of distributed applications, specially, the peer-to-peer ones.

Keeping this in mind, Davies, Friday, and Storz (2004) set up their own approach for getting benefit from grids. The authors underline common characteristics of grids and pervasive computing and use this as a starting point for defining a grid-based test bed of pervasive applications.

The ability of testing and developing pervasive applications in an environment that simulates real environments is certainly a great contribution. Problems that are difficultly detected inside traditional development environments are easier identified and fixed when applications are tested in appropriate environments.

Nevertheless, some questions remain open. For instance, grids are traditionally built over wired networks and smart spaces are composed of wireless devices. In order to try to be closer to real smart spaces, such a grid-based test bed must simulate the network interfaces of mobile clients, including bandwidth, power consumption and coverage area. Another point of investigation is the gap of performance between small portable devices and computers of wired grids. Tests performed in hosts rather powerful than the real devices where the applications should run may hide problems that should be identified in this phase of tests. After all, it is still needed to know whether the tested application is the same one to be deployed in mobile devices. This becomes an issue due to differences in architectures, as well as hardware and software-specific optimizations that may contrast the results given in the test and deployment phases.

**Using Grids to Collect and Process Data from Sensor Networks**

Embedding computation in everyday objects means, most of time, deploying sensors and actuators across environments. Sensors are responsible for bringing to the computational world information about the physical world. Conversely, actuators obtain information from the computational world and are responsible for transforming information into actions in the physical world. Sensors may produce large amounts of data that must be processed and interpreted before an action is taken. Processing large amounts of data generally implies the use of large amounts of computational power. Therefore, grids may play an important role in gathering and processing information from sensor networks (Barratt et al., 2003; Gaynor, Moulton, Welsh et al., 2004).

In this context, Gaynor et al. (2004) discuss challenges and research directions for integrating sensor networks to a standard wired grid. Despite all challenges, this approach seems to balance advantages from both technologies. In fact, this alternative requires not much effort to be applied, since it is a direct application of grids. As posed by Gaynor et al. (2004), data standardization is possibly a challenging task in providing such architecture. Once collected from sensors, it is important to share data in a uniform manner. Thus, different applications and devices may consume data without being overburden with logics for transforming data to an understandable format.
THE GRID PERSPECTIVE

Traditionally, grid computing research has been focusing on high performance. Even with the aim change for sharing any kind of computational resources instead of only CPU cycles and storage space, the grid community is still hungry for more computational power. In this context, the main focus of the grid community is to use mobile devices in the grid for solving computational tasks and storing files. In what follows, approaches for getting benefit of pervasive computing inside the grid research are summarized.

Augmenting Grid Resources through Mobile Devices

The general idea is to use small mobile devices as nodes of high performance grids (Litke, Skoutas, & Varvarigou, 2004; McKnight, Howison, & Bradner, 2004; Phan, Hung, & Dulan, 2002). Nodes connect to the grid as soon as they approximate to some access point and are disconnected from it when they leave the access point coverage area. While connected to the grid, mobile devices can receive and submit tasks.

This may sound a little atypical considering all restrictions of small mobile devices. However, research groups around the whole world bet in the whole number of small devices working together instead of the computational power of one lone device. Phan et al. (2002) define an architecture as including mobile devices into a wired grid. Mobile devices enter the grid through proxies. This proxy runs an appropriate grid middleware, such as Globus or Condor, to publish itself as a node. Mobile devices are not visible to the rest of the grid. They only contribute to enlarge the computational power of the proxy, which is responsible for decomposing and spreading received work across the mobile devices linked to it.

Besides all drawbacks discussed before, this approach has yet the serious problem of how a given task can be broken into smaller tasks for sharing with mobile devices. Definitely, this is a non-trivial problem and may overburden grid users, who will need to provide the means for a proxy node to split a task into small ones.

In the grid perspective, augmenting the number of devices supported by the infrastructure is always a good deal. Both mobile devices and grid have an opportunity to obtain benefits from this merging. Moreover, constant advances in mobile technology trend to reduce the drawbacks of using mobile devices for high processing. Nonetheless, the actual technology still poses several challenges for this usage of mobile devices. In addition to issues already discussed, the mobile nature itself of these small devices may cause loss of work. For instance, when a portable device receives some work to perform and, just before concluding it, the device leaves the access point coverage area. There is also an economic question to be solved. Small mobile devices have clearly great potential advantages of being part of a grid in the sense that a grid may supply it with all the resources such devices may need. However, while part of a grid economy, mobile devices outwears themselves rather more than ‘conventional’ grid resources. Therefore, the grid economic model itself should adapt to address this new class of devices, making this integration profitable for both mobile and grid users.

Mobile/Wireless Grids

Mobile grids have as main argument carrying grids where cables do not reach (Chu & Humphrey, 2004; Kurkovsky & Bhagyavati, 2003; Park, Ko & Kim, 2003). The basic idea is to use high performance where the wired infrastructure is not available and clustering mobile devices is the last choice. In this context, software programs are ready to use resources of wired grids as well as switch to an ‘unplugged’ mode, where mobile devices collaborate to achieve better throughput for distributed processing.
As an example of this approach, Kurkovsky and Bhagyavati (2003) combine *mobile devices* to enable higher processing capacities for small devices. To achieve this, the defined architecture uses resources from an access point, for maintaining information about available devices in range and distribution of tasks among nodes. Any *mobile device* may submit tasks to the mobile grid. For this, the device must ask the access point to coordinate the distribution of tasks, re-submissions and collecting of results.

The idea of using on-demand wireless high processing sounds good, but certainly using a set of *mobile devices* in place of a wired grid does not solve the problem of high processing. However, this may be the only alternative on critical situations (Akogrimo, 2006).

Again, overloading these resource constrained devices trend to overdrive them, reducing thus their autonomy and without gaining anything with this. If we consider situations where portable devices accept tasks whose processing time spends more time then its autonomy, all effort for creating a grid in an ad-hoc fashion will be lost.

**Monitoring Grids and Controlling Applications through Portable Devices**

This is the more simplistic use of *mobile devices* in grids. The approach seems to have no great challenges to be transposed. On the other hand, the benefits obtained are rather limited. The general idea is quite simple. In a wired grid, it is enough to provide means for mobile clients to monitor relevant pieces of the grid, such as the grid healthy and application progress (Srinivasan, 2005; Taylor, Shields, Wang & Philp, 2003). Alternatively, users can somewhat control the grid operation, changing the way the work is doing.

The clear advantage of this approach is the low burden over portable devices. This approach requires low interaction and low data exchange between mobile clients and grid. There are also restrictions about the kind of data to be monitored. If large amounts of data are needed to be transferred to *mobile devices* then this approach may be inadequate owning to reasons already discussed in this chapter. This approach may be unsuitable in those scenarios where users want real-time access to monitoring data. Depending on the size of data, displaying a continuous stream of data may overdrive *mobile devices*. (Taylor et al., 2003) also relates to this approach. In this work Taylor et al. (2003) use a grid to simulate the formation of galaxies. *Mobile devices* may be used to monitor the workflow of grid services involved in the process.

**CONCLUSION**

In this chapter we discussed various approaches for combining grid and pervasive computing. The approaches were grouped into categories that were exemplified and criticized. The list is not exhaustive, but we believe it is sufficiently representative of how research groups are attempting to blend the technologies.

Resource constraints of *mobile devices* still are the bottleneck for this integration. In the perspective of pervasive computing, massive search applications (e.g., cryptographic key breakers) are the best example of class of application with all features for a successful integration between grids and pervasive computing—small pieces of data requiring intensive processing that produce more small pieces of data.

All efforts presented here are valid and, in well defined scenarios, they show the technologies can be successfully integrated. The approaches discussed in this chapter have their own application niche and, hence, a space where they can evolve. Nevertheless, our hopes are that while small *mobile devices* were so resource constrained, difficultly researchers will have both freedom and tools enough for developing their ideas. On the other hand, there are several problems
related to both grid and pervasive computing research: large-scale deployment, distributed resource management, economic models, interface standardization, heterogeneity, interoperability, scalability, runtime adaptability, fault tolerance, service composition, service discovery, security, resources semantic, and so on. Hence, while all the issues pointed out in this chapter were yet challenging tasks, both grids and Pervasive computing may contribute to each other by exchanging experiences.

KEY TERMS

Context Information: Any relevant information regarding the environment and its users. Smart spaces can use context information to deliver personalized services to users.

Embedded Devices: An embedded device is a special-purpose computer system, which is completely encapsulated by the device it controls. Examples of embedded devices include home automation products, like thermostats, sprinklers and security monitoring systems.

Grid Services: A kind of web service. Grid services extend the notion of web services through the adding of concepts regarding the WSRF specification, such as statefull services.

Intermittent Resources: Both in a grid and smart space, intermittent resources are any kind of resource, as computers or services, which may appear or disappear at any time.

Mobile Devices: Any low-sized portable device used to interact with other mobile devices and resources from smart spaces. Examples of mobile devices are cellular phones, smartphones, PDAs, notebooks and tablet PCs.

Peer-to-Peer: Architecture for distributed applications without central control where each participant acts both as client and server.

Sensor Networks: Network of many, spatially distributed devices using sensors to monitor conditions at different locations, such as temperature, sound, vibration, pressure, motion or pollutants.

Service-Oriented Architecture: Collection of services communicating with each other. Services are self-contained and do not depend on the context or state of other services.

Test Bed: In the context of software engineering, an execution environment configured for testing software.

ENDNOTES

1 Open grid service architecture
2 Quality of service

This work was previously published in the Encyclopedia of Networked and Virtual Organizations, edited by G.D. Putnik and M.M. Cunha, pp. 1223-1229, copyright 2008 by Information Science Reference, formerly known as Idea Group Reference (an imprint of IGI Global).
ABSTRACT

The advancement of technologies to connect people and objects anywhere has provided many opportunities for enterprises. This chapter will review the different wireless networking technologies and mobile devices that have been developed, and discuss how they can help organizations better bridge the gap between their employees or customers and the information they need. The chapter will also discuss the promising application areas and human-computer interaction modes in the pervasive computing world, and propose a service-oriented architecture to better support such applications and interactions.

INTRODUCTION

With the advancement of computing and communications technologies, people do not have to sit in front of Internet-ready computers to enjoy the benefit of information access and processing. Pervasive computing, or ubiquitous computing, refers to the use of wireless and/or mobile devices to provide users access to information or applications while the users are on the go. These mobile devices can be carried by the users, or embedded in the environment. In either case, these devices are connected, most likely through a wireless network, to the Internet or a local area network (LAN).

Mobile technologies come in a large variety and are ever changing. In order to gain the business value of pervasive computing, and at the same time keep the supporting cost under control, it is important to develop an architecture solution. A service-oriented architecture (SOA) would allow an enterprise to easily provision functions to be accessible by certain types of pervasive channels. A service-oriented architecture would also make it possible to quickly integrate data generated by pervasive devices and make them available in the form of an information service.

In this chapter, we will first look at the communication networks and mobile devices that create the various information-access and information-generation touch points in a pervasive...
computing environment. Then we will discuss the applications and interaction models for pervasive computing. Finally, we will describe a service-oriented architecture that an enterprise can adopt in order to effectively and efficiently support pervasive computing.

MOBILE COMMUNICATION NETWORKS

Mobile communication technologies range from personal area networks (PANs; a range of about 10 meters) and local area networks (a range of about 100 meters) to wide area networks (WANs; a few kilometers). From a network-topology perspective, most networks are based on a client-server model. A few are based on the peer-to-peer model.

Wireless PANs

A wireless personal area network allows the different devices that a person uses around a cubicle, room, or house to be connected wirelessly. Such devices may include the computer, personal digital assistants (PDAs), cell phone, printer, and so forth.

Bluetooth is a global de facto standard for wireless connectivity (Bluetooth SIG, 2005). The technology is named after the 10th-century Danish King Harald, who united Denmark and Norway and traveled extensively.

HomeRF is an early technology for wireless home networking, first marketed in 2000.

The Institute of Electrical Engineers (IEEE) 802.15 wireless-PAN effort (IEEE, 2005a) focuses on the development of common standards for personal area networks or short-distance wireless networks. One technology out of this effort is ZigBee, which is based on the IEEE 802.15.4 standard.

ZigBee is a low-cost, low-power-consumption, wireless communication-standard proposal (ZigBee Alliance, 2005). Formerly known as FireFly, ZigBee is being developed as the streamlined version of HomeRF. A streamlined version would allow most of the functionality with less integration and compatibility issues.

ZigBee’s topology allows as many as 250 nodes per network, making the standard ideal for industrial applications. Radio-frequency-based ZigBee is positioned to eventually replace infrared links. To achieve low power consumption, ZigBee designates one of its devices to take on the coordinator role. The coordinator is charged with waking up other devices on the network that are in a sleep mode, moments before packets are sent to them. ZigBee also allows coordinators to talk to one another wirelessly. This will allow for opportunities for wireless sensors to continuously communicate with other sensors and to a centralized system.

For enterprise computing, the wireless PANs are within the corporate firewall. They do not

create new requirements for the enterprise architecture to extend access to applications. However, they do require security measures to make sure the device that is receiving information is a recognized device. It also creates an opportunity for the computing infrastructure to potentially know where a particular device, and most likely the associated user, is located. How these are handled will be discussed later in the description of the proposed service-oriented architecture.

**Wireless LANs**

The set of technical specifications for wireless local area networks (WLANs), labeled 802.11 by IEEE, has led to systems that have exploded in popularity, usability, and affordability. Now wireless LAN can be found in many organizations and public places.

With a wireless LAN, a user’s device is connected to the network through wireless access points (APs). APs are inexpensive—many are available for less than $100—and will usually work perfectly with little or no manual configuration.

Wireless LANs use a standard, called IEEE 802.11, that provides a framework for manufacturers to develop new wireless devices. The first two standards released for wireless LANs were 802.11b and 802.11a. The 802.11b standard was used in most wireless devices in the early adoption of wireless LAN. A new standard, called 802.11g, combines data-transfer rates equal to 802.11a with the range of an 802.11b network. Mimo technology allows the use of two or more antennas operating on that channel. Normally, this would cause interference degradation of the signal because the radio waves would take different paths—called multipath distortion. However, Mimo technology allows the use of two or more antennas operating on that channel. Normally, this would cause interference degradation of the signal because the radio waves would take different paths—called multipath distortion. However, Mimo technology corrects for the multipath effects. IEEE is standardizing the technology as IEEE 802.11n.

For an enterprise, wireless LAN technologies allow pervasive information access throughout the campus. Employees with authorized mobile devices such as wireless laptops and PDAs will be able to get online wherever they are on the campus.

Table 2 summarizes the wireless LAN technologies.
A wireless metropolitan area network (MAN; also referred to as broadband wireless access, or WiMAX) can wirelessly connect business to business within the boundary of a city. It is becoming a cost-effective way to meet escalating business demands for rapid Internet connection and integrated data, voice, and video services.

Wireless MANs can extend existing fixed networks and provide more capacity than cable networks or digital subscriber lines (DSLs). One of the most compelling aspects of the wireless MAN technology is that networks can be created quickly by deploying a small number of fixed-base stations on buildings or poles to create high-capacity wireless access systems.

In the wireless MAN area, IEEE has developed the 802.16 standard (IEEE, 2005b), which was published in April 2002, and has the following features.

- It addresses the “first mile-last mile” connection in wireless metropolitan area networks. It focuses on the efficient use of bandwidth between 10 and 66 GHz.
- It enables interoperability among devices so carriers can use products from multiple vendors. This warrants the availability of lower cost equipment.
- It defines mechanisms that provide for differentiated quality of service (QoS) to support the different needs of different applications. The standard accommodates voice, video, and other data transmissions by using appropriate features.
- It supports adaptive modulation, which effectively balances different data rates and link quality. The modulation method may be adjusted almost instantaneously for optimal data transfer. Adaptive modulation allows efficient use of bandwidth and fits a broader customer base.

The WiMAX technical working group has developed a set of system profiles, standards for protocol-implementation conformance, and test suites (http://www.wimaxforum.org).

One particular technology for WiMAX is non line of sight (NLOS) networking (Shrick, 2002). NLOS networks provide high-speed wireless Internet access to residential and office facilities.

NLOS uses self-configuring end points that connect to a PC (personal computer). The end point has small attached antennas and can be mounted anywhere without the need to be oriented like satellite antennas. Two major vendors are Navini Networks and Nokia.

With the wireless MAN technology, enterprises can quickly set up a network to provide wireless access to people in a certain area. It is very useful in situations such as an off-site working session or meeting.

**Wireless NANs**

Wireless neighborhood area networks are community-owned networks that provide wireless broadband Internet access to users in public areas (Schwartz, 2001). To set up a wireless NAN, community group members lend out access to the Internet by linking wireless LAN connections to high-speed digital subscriber lines or cable modems. These wireless LAN connections create network access points that transmit data for up to a 1-kilometer radius. Anyone possessing a laptop or PDA device equipped with a wireless network card can connect to the Internet via one of these community-established access points.

Wireless NANs have been established in more than 25 cities across the United States. Community-based networks differ from mobile ISPs (Internet service providers) such as MobileStar and Wayport that offer subscribers wireless access to the Internet from hotels, airports, and coffee shops. Wireless NANs extend access to consumers in indoor as well as outdoor areas, and the access is typically offered at no charge. For instance, NYC Wireless (http://www.nyc-wireless.net) provides Internet access to outdoor public areas in New York City. In addition, this organization is negotiating with Amtrak to bring wireless Internet access to Penn Station.

Enterprises could leverage the existing wireless NANs and equip employees with the right devices and security mechanisms in order to use these wireless networks to securely connect to the corporate network.

**Wireless WANs**

Wireless wide area networks are commonly known as cellular networks. They refer to the wireless networks used by cell phones.

People characterize the evolution of wireless WAN technology by generation. First generation (1G) started in the late 1970s and was characterized by analog systems. The second generation of wireless technology (2G) started in the 1990s. It is characterized by digital systems with multiple standards and is what most people use today. 2.5G and 3G are expected to be widely available 1 to 3 years from now. 4G is being developed in research labs and is expected to launch as early as 2006.

Wireless WAN originally only offered voice channels. Starting from 2G, people have used modems to transmit data information over the voice network. More recent generations offer both voice and data channels on the same cellular network.

One of the major differentiating factors among the wireless generations is the data transmission speed in which the wireless device can communicate with the Internet. The table below is a comparison of the data transmission rates of the 2G, 2.5G, 3G, and 4G technologies (3Gtoday, 2005). Both 2G and 2.5G include different technologies with different data transmission rates. Global Systems for Mobile Communications (GSM) and Code Division Multiple Access (CDMA) are 2G technologies. General Packet Radio Service (GPRS), CDMA 1x, and Enhanced Data for GSM Environment (EDGE) are 2.5G technologies.

In the United States, cellular carriers Verizon and Sprint use CDMA technology. Cingular uses GSM, GPRS, and EDGE technologies. Both Verizon and Sprint have rolled out their CDMA 1x
services, which is 2.5G. Cingular has rolled out GRPS service and is starting to roll out EDGE service in selected markets.

Wireless WANs are available wherever cell phones can be used. For now, they are the most pervasive wireless networks. By subscribing to a service plan, an enterprise user’s laptop computer or other mobile device can connect to the Internet through the service provider’s cellular towers.

**Ultrawideband (UWB)**

Traditional radio-frequency technologies send and receive information on particular frequencies, usually licensed from the government. Ultrawideband technology sends signals across the entire radio spectrum in a series of rapid bursts.

Ultrawideband wireless technology can transmit data at over 50 Mbps. A handheld device using this technology consumes 0.05 milliwatts of power as compared to hundreds of milliwatts for today’s cell phones. Ultrawideband signals appear to be background noise for receivers of other radio signals. Therefore it does not interfere with other radio signals. Ultrawideband is ideal for delivering very high-speed wireless-network data exchange rates (up to 800 Mbps) across relatively short distances (less than 10 meters) with a low-power source.

Another feature of ultrawideband signals is that they can penetrate walls. Therefore, this technology would allow a wireless device to communicate with a receiver in a different room. This feature can also be used to detect buried bodies, people in a building, or metal objects in concrete.

**Mesh Radio and Mess Networks**

Mesh radio is a wireless network technology that operates in the 28-GHz range of the radio spectrum and provides high-speed, high-bandwidth connectivity to the Internet (Fox, 2001). A mesh radio network consists of antennas connected in a web-like pattern to a fiber-optic backbone. A single antenna attached to the roof of a building could provide Internet access to all of the subscribers residing in the building. Each node on the network has a small, low-power, directional antenna that is capable of routing traffic for other nodes within a 2.8-kilometer radius. In contrast to other wireless networks, mesh radio avoids many of the line-of-sight issues between the base station and each node on the network. Consequently, the configuration of mesh radio reduces the chance of encountering physical obstructions that could impede access to the network.

Mesh radio networks are being developed in two different ways. CALY Networks has devel-
Leveraging Pervasive and Ubiquitous Service Computing

oped a system that utilizes the Internet protocol (IP) as its communication mechanism, while Radiant Networks has created a system that communicates using the asynchronous transfer mode (ATM). Providers of mesh radio services include British Telecommunications, TradeWinds Communications (http://www.tnsconnects.com), and Nsight Teleservices (http://www.nsighttel.com).

Features of mesh radio include the following:

- Provides upload and download data rates of up to 25 Mbps
- Supports up to 600 subscribers per square kilometer without degradation of service
- Provides cost-effective access to broadband services in rural communities or urban areas
- Increases network capacity and resilience as the customer base grows

Different from the mesh radio technology, mesh networks enable wireless devices to work as a peer-to-peer network, using the handsets themselves instead of the radio towers to transmit data (Blackwell, 2002). Each handset would be capable of transmitting data at rates from 6 Mbps to 18 Mbps. This technology can be used for a group of users or devices communicating with each other in a peer-to-peer mode without needing an established wireless network. The technology was developed by Mesh Networks Inc., which has been acquired by Motorola.

Sensor Networks

Motes (also called sensor networks or Smart Dusts; Culler & Hong, 2004) are small sensing and communication devices. They can be used as wireless sensors replacing smoke detectors, thermostats, lighting-level controls, personal-entry switches, and so forth. Motes are built using currently available technology and are inexpensive enough to be deployed in mass quantities. Depending on the sensors and the capacity of the power supply, a mote can be as big as 8 cubic centimeters (the size of a matchbox) or as small as one cubic millimeter.

Motes are the result of a joint effort between Defense Advanced Research Projects Agency (DARPA) and the University of California, Berkeley, research labs. Most initial applications are positioned to helping the military for tasks such as surveillance of war zones, the monitoring of transportation, and the detection of missiles and/or biological weapons. Commercial mote sensors are available from Crossbow Technology.

A mote is typically made up of the following:

- A scanner that can scan and measure information on temperature, light intensity, vibrations, velocity, or pressure changes
- A microcontroller that determines tasks performed by the mote and controls power across the mote to conserve energy
- A power supply that can be small solar cells or large off-the-shelf batteries
- TinyOS, an open-source software platform for the motes. TinyOS enables motes to self-organize themselves into wireless network sensors.
- TinyDB, a small database that stores the information on a mote. With the help of TinyOS, the mote can process the data and send filtered information to a receiver.

These motes enable enterprises to constantly collect important information and send the information to the appropriate server for processing so that the appropriate response can be initiated when necessary. The motes become the generator of pervasive information that reflects the status of business processes or environmental conditions.
Pervasive Devices

Pervasive devices come in different forms and shapes. Compared to a networked computer, some pervasive devices, such as landline or cell phones, are more widely available. Other devices are simply more portable and thus can be easily carried around. Yet other devices are embedded in the environment and are able to deliver specialized information. In terms of their functions, some are for accessing the Internet, some are just for entering information while the user is on the go, and others are for storing large amounts of information and can be easily carried around.

Traditional Telephones, Pagers, and Cell Phones

Traditional landline telephone has been the most pervasive communication device around the world. Voice markup languages such as VoiceXML (voice extensible markup language; Rubio, 2004), together with supporting technologies such as the voice browser and voice gateway, has made the traditional telephone yet another device for connecting the user to the Internet. With speech recognition, users can choose to use touch tone or simply say what they need. Figure 1 shows how a telephone can be used to connect to the Internet.

1. The user dials the number from any phone (landline or mobile).
2. The call is routed to the corresponding voice gateway, which maps the phone number to a particular application hosted at the enterprise network.
3. The voice gateway knows the URL (uniform resource locator) of the application. It uses an HTTP (hypertext transfer protocol) request to fetch the first dialog of the application.
4. The enterprise Web server and application server return the dialog to the gateway in the form of a VoiceXML document.
5. The gateway interprets the VoiceXML document, plays the greeting, and asks the user for input. Now the user can use touch tone or speech to provide input. Based on the user input and the application logic as described in the VoiceXML file, the voice gateway decides what dialog to fetch next from the enterprise network.

Pagers allow users to receive alerts with a limited amount of text. With two-way pagers, users can also reply with a text message.

With cell phones (not smart phones), besides the same communication capabilities of a landline telephone, most users can use short-message service (SMS) to send and receive text messages. This is good for near-real-time conversational communications.

Figure 1. Voice gateway connects the phone network with the data network
Smart Phones, Wireless PDAs, and Blackberry Devices

Smart phones are cell phones that have both voice and data capabilities. Such a cell phone comes with a mini Web browser and thus can be used to access Internet content. However, since the smart phones typically have rather small screens, they can only access pages specifically designed for small screens and coded in a special markup language such as Wireless Markup Language (WML). Some smart phones are equipped with a computing platform such as the Java Virtual Machine that can run applications written in J2ME (Java 2 Micro Edition).

Wireless PDAs typically have larger screens than cell phones and can directly access HTML (hypertext markup language) pages. Some wireless PDAs can also be used to make phone calls, and are referred to as PDA phones. Since many people prefer to carry only one of such mobile device around, there is a competition between PDA phones and smart phones, a war in which the smart phones seem to be winning.

ViewSonic (http://www.viewsonic.com) made a super-sized PDA, called the ViewPad, that offers a regular 800x600-pixel screen. The ViewPad can be a very useful mobile device when regular screen size is a necessity while light weight and zero-boot-up time are also desired.

Blackberry devices made by Research in Motion (http://www.rim.com) has been a big success for enterprise users as they provide a very convenient way for reading and typing e-mails while being away from the office.

Laptop or Tablet PCs with Wireless Access

When size and weight are not inhibitive, mobile users may choose to carry a laptop or tablet PC while on the go. These mobile PCs use wireless cards to connect to either a wireless LAN or wireless WAN. Many such laptops now have built-in wireless LAN cards, and have slots for users to insert a wireless WAN card such as the AirCard made by Sierra Wireless (http://www.sierrawireless.com). An enterprise also needs to be prepared to provide support to mobile users in order to help them connect to the Internet through Wi-Fi hot spots (Hamblen, 2005).

Wireless LAN is often available at a corporation campus, or at public hot spots such as many airports and Starbucks Cafés. Wireless WAN is available wherever cellular service is available for the specific provider that the wireless card is registered with.

IP Phones

IP phones are telephones that use a TCP/IP (transmission-control protocol/Internet protocol) network for transmitting voice information. Since IP phones are attached to the data network, makers of such devices often make the screens larger so that the phones can also be used to access data. What makes IP phones pervasive devices is that a user who is away from his or her own desk can come to any IP phone on the same corporate network, log in to the phone, and make the phone work as his or her own phone. The reason is for this is that an IP phone is identified on the network by an IP address. The mapping between a telephone number and an IP address can be easily changed to make the phone “belong” to a different user.

In terms of the information-access capability, Cisco (http://www.cisco.com) makes IP phones that can access information encoded in a special XML format. Example applications on the phone include retrieving stock quotes, flight departure and arrival information, news, and so forth.

Pingtel (http://www.pingtel.com) developed a phone that runs a Java Virtual Machine. This makes the phone almost as powerful as a computer.

Mitel (http://www.mitel.com) made an IP phone that allows a user to dock a PDA. With this capability, users can go to any such IP phone,
Leveraging Pervasive and Ubiquitous Service Computing

dock their PDA into the phone, and immediately have their address books on the PDA available to the telephone. Users can also have their personal preferences transferred from the PDA to the phone and start to use the phone the way they prefer. In addition, users can benefit from new applications on the PDA, such as portable voice mail and dialing by the address book.

The Mitel IP phone seamlessly blends the wired and wireless world for the user so that they are no longer dealing with two separate communication tools. It also provides users with location transparency within the network.

Orbs (Ambient Devices)

Orbs are simple devices that convey information at a glance in a manner that is easy to observe and comprehend (Feder, 2003). Orbs only present a visual indication of the data, not detailed information or actual numbers. Orbs come in different forms. One common orb is a simple globe that changes color and intensity. Other forms include the following:

- Wall panels that adjust color or blink
- Pens, watch bezels, and fobs that change color
- Water tubes that vary the bubble rate
- Pinwheels that change speed

Orbs operate via wireless pager networks under the command of a server. This server gathers pertinent information from sources, including the Web, condenses it to a simple value, and periodically sends the information to the orbs.

Orbs are currently available from several retailers. The wireless service costs about $5 per month per device. Ambient Devices (http://www.ambientdevices.com) sells orbs and provides the communications service.

The information displayed by orbs is configurable. There are currently available data feeds for stock-market movement and weather forecasts.

Input Technologies: Dictation, Anoto Pen, and Projection Keyboard

Two natural ways for mobile users to input information are speech and handwriting.

Speech input can be at two levels: question-and-answer vs. dictation. Question-and-answer speech input is useful for entering structured information where the answers can be predefined using a grammar. Dictation technology allows users to speak freely and tries to recognize what the user has said. Diction technology typically requires a training phase to tune the speech recognizer to each particular speaker in order to achieve high recognition accuracy. Leading dictation products are Dragon NaturallySpeaking from ScanSoft (http://www.scansoft.com) and ViaVoice from IBM (http://www.ibm.com).

The Swedish company Anoto (http://www.anoto.com) invented a technology for pen-based input (McCarthy, 2000). It consists of a digital pen that feels like a regular ballpoint pen, a special paper with patterns of dots printed on it, and a wireless technology such as Bluetooth that sends handwritten information stored in the pen to a computer. As the user writes, the pen not only records what has been written, but also the order in which the user writes it. Anoto has partnered with companies such as Logitech (http://www.logitech.com) and Nokia (http://www.nokia.com) to bring this technology to end users.

For users who want to use a keyboard without carrying one, Canesta (http://www.canesta.com) developed the projection keyboard, in which the image of a keyboard is projected on a surface. By typing on the projection keyboard, information is entered into the associated PDA device.

Application Scenarios

From an enterprise’s perspective, the following applications areas are where pervasive computing brings business value.
Leveraging Pervasive and Ubiquitous Service Computing

- Allow employees to stay in touch with phone calls, voice mail, e-mail, and so forth while being away from the office.
- Give employees access to information or transactions via mobile devices while on the road.
- Provide employees with access to the corporate network from anywhere on the Internet (i.e., remote access).
- Send location-based information to employees and customers.
- Monitor device status, perimeter security, and so forth using a wireless sensor network.

COMMUNICATION: UNIFIED COMMUNICATION AND INSTANT COMMUNICATION

With cell phones and pagers, it is not very hard to keep mobile users in touch. But some pervasive communication technologies have reached a higher level. Let us look at two such technologies: unified communication and instant communication.

Unified communications refers to technologies that allow users access to all their phone calls, voice mails, e-mails, faxes, and instant messages as long as they have access to either a phone or a computer. With a computer, a software phone allows the user to make or receive phone calls. Voice-mail messages can be forwarded to the e-mail box as audio files and played on the computer. Fax can be delivered to the e-mail box as images. With a phone, a user can listen to e-mail messages that the system would read using the text-to-speech technology. A user can request a fax to be forwarded to a nearby fax machine.

Unified communications services are offered by most traditional telecommunications technology providers such as Cisco, Avaya, and Nortel.

Instant communication refers to the ability of reaching someone instantly via a wearable communication device. Vocera (http://www.vocera.com) offers a system that uses 802.11b wireless local area networks to allow mobile users to instantly communicate with one another. Each user only needs to have a small wearable device to stay connected. To reach someone, the user would only need to speak a name, a job role, a group, or a location to the system, and the system will take care of the rest. By combining a small wearable device and the speech-recognition capability, Vocera offers a highly usable solution for mobile communication within an organization.

The functions and features of Vocera include the following:

- Instant communication via a small wearable device and speech commands
- Hands-free communication. Except for pressing the button to start and stop a conversation, a user’s hands are free during the communication.
- Flexibility in how to specify the recipients. A user can use a name, role, group, or location to tell the system whom to contact.
- The option of having a conversation or leaving a message, for both one-to-one and group communications
- Call controls such as call transfer, blocking, or screening
- Outside calling through the private branch exchange (PBX). The Vocera server can be connected to the PBX to allow users of Vocera to contact people outside the organization.

The Vocera technology has been well received in organizations such as hospitals where users’ hands are often busy when they need to communicate with others.
Leveraging Pervasive and Ubiquitous Service Computing

Mobile Access to Information and Applications

Organizations can benefit significantly by allowing mobile access to information and applications. Here are a few examples.

Sales-Force Automation

Salespeople are often on the road. It is important for them to have access to critical business information anywhere at anytime. Pervasive access to information increases their productivity by using their downtime during travel to review information about clients and prospects, about the new products and services they are going to sell, or to recap what has just happened during a sales event when everything is still fresh in their memory. Being able to use smart phones or wireless PDAs to conduct these activities is much more convenient for salespeople as opposed to having to carry a laptop PC.

Dashboard or Project-Portfolio Management

For busy executives, it is very valuable for them to be able to keep up to date on the dashboard while they are away from the office and to take actions when necessary. It is also very helpful for them to be able to look at the portfolio of projects they are watching, update information they have just received during a meeting or conversation, and take notes or actions about a specific project.

Facility Management and Other On-Site Service Applications

Mobile access to information can significantly boost the productivity of on-site service people such as facility- or PC-support staff. With mobile access, they can retrieve ticket information on the spot, update the ticket as soon as they are done with the work, and get the next work order without having to come back to the office. Mobile access also reduces the amount of bookkeeping, which requires a lot of manual intervention, and thus reduces the chance of human errors.

Remote Access to Corporate Network

Allowing employees access to the corporate network from anywhere on the Internet could certainly bring convenience to employees and boost productivity. There are two primary fashions of allowing remote access.

One approach is through a technology called virtual private network, or VPN. This typically requires the user to carry a laptop offered by the employer. Once the user is connected to the Internet, a secure connection (called a VPN tunnel) is established between the laptop and the corporate network after both user and device are authenticated. Then the user will have access to all the information and applications just as if the user were in the office.

The other approach does not require the user to carry a corporate laptop. It simply requires that the user has access to a Web browser. In this case, for security reasons, two-factor authentication is often employed, in which the user not only needs to provide a user ID and password, but also something else, such as the security code generated by a hard token. With this approach, an enterprise can choose which applications to make available for remote access. Terminal service technology offered by Citrix (http://www.citrix.com) can be used to offer browser-based remote access to applications, both Web based and desktop based.

Location-Based Services

A special type of pervasive application is location-based service. With wireless LANs, when a mobile user is in the vicinity of an access point,
location-specific information can be delivered to
the user’s mobile device. With wireless WANs, a
user’s location can be determined by the cellular
tower(s) that the user’s handset is communicating
with, or by the GPS (Global Positioning System)
receiver the user is using. Location-based services
include pushing information about local busi-
nesses, sending promotions to the user’s device
based on the user’s profile and preferences, and
showing meeting agendas and meeting material
if the user is on the meeting attendee list for the
room at the time.

If location needs to be accurately determined,
an ultrasonic location system called the bat system
can be used. This 3-D location system uses low
power and wireless technology that is relatively
inexpensive. An ultrasonic location system is
based on the principle of trilateration: position
finding by the measurement of distances. A short
pulse of ultrasound is emitted from a transmitter
or bat that is attached to a person or object to be
located. On the ceiling are receivers mounted at
known points. These receivers can measure the
pulse and length of travel.

An ultrasonic location system is composed of
three main components.

• **Bats:** Small ultrasonic transmitters worn by
  an individual or on an object to be located
• **Receivers:** Ultrasonic signal detectors
  mounted in the ceiling
• **Central controller:** Coordinator of the bats
  and receivers

To locate a bat, the central controller will
send the bat’s ID via a 433-MHz bidirectional
radio signal. The bat will detect its ID through
the embedded receiver and transmit an ultrasonic
signal containing a 48-bit code to the receiver in
the ceiling. The central controller will measure
the elapsed time that it took for the pulse to reach
the receiver. The system developed at the AT&T
Cambridge facility can provide an accuracy of 3
centimeters.

Overall, location-based services are still in
research mode. Once the technology becomes
mature and “killer apps” are identified, there
could be an explosive adoption.

**User-Interaction Models**

In the context of pervasive computing, it is usually
inconvenient, if not impossible, for the user to
enter text using a regular keyboard. Sometimes,
it is also inconvenient for the user to read text.
Therefore, other input and output mechanisms
have to be employed.

Nontraditional input mechanisms include
speech recognition, gesture, touch screen, eye
gazing, software keyboard, and projection key-
board. Among these, a combination of speech-
recognition and pen-based touch-screen input is
most natural for most situations. This is also what
PDAs and tablet PCs typically offer.

Nontraditional output mechanisms include
converting text to speech and using sound,
blinking, and vibration to convey information
(as in ambient computing described earlier in
this chapter).

Multimodal interaction allows a user to choose
among different modes of input and output. For
mobile users, speech is typically the most conve-
nient way for input, while visual means may still
be the most powerful way of seeing the output
(especially when the output includes pictures or
diagrams).

Kirusa (http://www.kirusa.com) has developed
technologies to support multiple levels of multi-
modal interaction. SMS multimodality allows users
to ask a question in voice and have the answers
delivered to their mobile devices in the form of
an SMS message. Sequential multimodality al-
lows users to use the interaction mode deemed
most appropriate for each step of the process.
Simultaneous multimodality lets users combine
different input and output modes at the same time.
For example, for driving directions, a user can
Leveraging Pervasive and Ubiquitous Service Computing

say “I need directions from here to there,” while pointing to the start and end points.

Both IBM and Microsoft have developed technologies that will support multimodal interaction. IBM’s solution is based on the XHTML+VoiceXML (or simply X+V) specification. Microsoft’s solution is based on the speech application language tags (SALT) specification, which defines speech input and output tags that can be inserted into traditional Web pages using XHTML.

Besides deciding on what interaction mode to support, much effort is needed to apply user-centered design in order to deliver a good use experience for mobile users (Holtzblatt, 2005).

A Service-Oriented Architecture to Support Pervasive Computing

For an enterprise to leverage pervasive computing, instead of deploying various point solutions, the better way is to build an architecture that is well positioned to support pervasive devices and usage. In order to provide mobile users with maximum access to enterprise information and applications with customized interaction methods and workflow, and at the same time minimize the extra cost in supporting pervasive access, a service-oriented architecture should be established.

The following picture shows a service-oriented architecture that supports pervasive computing. Let us look at this architecture from the top to the bottom.

• Users access applications from different devices. Some devices, such as the regular telephone, have only the voice channel. Some, such as the Blackberry devices, only have the visual display. Others may have both voice and visual channels. The size of the visual display ranges from 1 inch for cell phones, several inches for the PDA and Blackberry, and 15 or more inches for laptops.

• The user devices may be on different network connections, ranging from wireless LAN and wireless WAN to telephone networks.

• Users access applications through the applications’ end points. This could be a URL, a phone number, or a start screen stored on the end user’s device.

• The pervasive layer sits between the application end points and the SOA layer to provide services to specifically support the mobile users.

• The device identification engine uses a unique ID to identify the device the user is using. This requires the augmentation of some of the communication protocols to include a universally unique ID (such as the radio frequency identifier, or RFID) of the device that is initiating the request. With this ID, the system can uniquely identify the device and thus have knowledge of its capabilities, the associated user, and so forth. The ID information is also passed to the security service in the SOA layer to help decide whether the user is authorized to access the application.

• The access-control engine uses information about the device and the communication channel it is coming from to determine the best way to communicate with the device: voice only, visual only, SMS, or some type of multimodal interaction.

• Based on the desired interaction mode with the user, the content-transformation engine either calls the appropriate version of the application or dynamically transforms the information into the appropriate markup language: HTML, WML, VoiceXML, X+V, and so forth, using the eXtensible Stylesheet Language transformation (XSLT) technology.
• The location-determination service uses mechanisms built into the networks to determine the geographic location of the user, and then decides whether the information should be tailored based on the location and whether additional location-based information should be pushed to the user.
• The session-persistence engine uses the device ID and user-identity information to keep the user in the same session while the user is roaming from one network to another, or from disconnected mode to connected mode again during a short period of time. For smart-client applications, where data may be temporarily stored on the device when connection is lost, the session-persistence layer would also take care of synchronizing the data on the device with data on the server.

Figure 2. A service-oriented architecture that supports pervasive computing
• The business-application composition layer uses information received from the pervasive layer to determine how to integrate the business services together to best fit the need of this mobile user.

• The SOA layer provides the business services and technical services that are integrated together through the enterprise service bus. The business services can be built using Net-centric technologies such as Java or Microsoft .NET, or they can be built based on existing legacy business functions such as customer information control system (CICS) transaction and stored procedures. They can also be based on business functions built using third-party tools or existing in-house business modules developed in C or C++, COBOL, and so forth.

After the establishment of such an architecture (which can be gradually built across multiple projects), when building an application that supports pervasive access, business services are either reused or built. When an existing business service is reused, the project team needs to go through the service’s specification to verify that the service will work well with the pervasive layer to support all the pervasive channels that the application is going to support. If not, the first thing the project team should try to modify is the pervasive layer. If the issue really lays in the fact that the business service is not a “pure” service, that is, the service is tied to access methods, then the service needs to be either modified or wrapped in order to support the new requirements. When such a modification occurs, the service needs to be made backward compatible, and existing applications that use the service need to be regression tested. Eventually, the service definition needs to be modified to reflect the changes.

With this architecture, when a new pervasive access channel appears, or there is a change in an existing channel, then the only thing that needs to be modified is the pervasive channel. All business services can remain the same.

FUTURE DIRECTIONS

Moving forward, there needs to be much research and development work on building a system infrastructure that can use different sources of information to judge where the user is, and what devices and interaction modes are available to the user during a pervasive session. This will enable smarter location-based information push to better serve the user.

A related research topic is how to smoothly transition an interaction to a new device and interaction mode as the user changes locations and devices. Some initial work on this subject, referred to as seamless mobility, is being conducted at IBM and other organizations.

Another area that deserves much attention is the proactive delivery of information that users will need based on their profiles and information such as activities on their calendars or to-do lists. This relates to previous research efforts on intelligent personal assistants with integration into the pervasive computing environment.

INTRODUCTION

The fast development on microelectronics has promoted the increase on the computational power of hardware components. On the other hand, we are facing a significant improvement on energy consumption as well as the reduction of the physical size of such components. These improvements and the emergence of wireless networking technologies are enabling the development of small and powered mobile devices. Due to this scenario, the so-called pervasive computing paradigm, in-
Service Provision for Pervasive Computing Environments

introduced by Mark Weiser in 1991 (Weiser, 1991) is becoming a reality. Such a paradigm envisions a world where environments are inhabited by computing devices, all of them seamlessly integrated into peoples’ lives, and effectively helping to carry on their daily tasks.

Among others, one major characteristic of Weiser’s vision is that each device in an environment becomes a potential client or provider of resources. Not surprisingly, pervasive computing environments are becoming dynamic repositories of computational resources, all of them available to mobile users from the palm of their hands. However, devices can unpredictably join and leave such environments. Thus, resources can be dynamically made available or unavailable. Such a scenario has a great impact on the way that resources are found and used. In the case of static environments, such as the Web, it is reasonable to look up and access resources, such as Web pages, knowing the address of their providers beforehand. On the other hand, for dynamic environments, such as the pervasive computing ones, this is not a reasonable approach. This is due to the fact that one cannot guarantee that the provider of a resource will be available at any moment, because it may have left the environment or simply turned off. A better approach would be to discover these resources based on their descriptions, or any other feature that does not require the client to know the specific address of their providers.

To this end, some of the current pervasive computing solutions, like Wings (Loureiro, Bublitz, Oliveira, Barbosa, Perkusich, Almeida, & Ferreira, 2006), Green (Sivaharan, Blair, & Coulson, 2005), RUNES (Costa, Coulson, Mascolo, Picco, & Zachariadis, 2005), and Scooby (Robinson, Wakeman, & Owen, 2004), are making use of a novel approach from the branch of distributed applications, the service-oriented computing paradigm (Papazoglou, 2003; Huhns & Singh, 2005). This is due to the fact that such a paradigm provides a crucial element for pervasive computing systems, the ability for dynamically binding to remote resources (Bellur & Narendra, 2005), which enables mobile devices to find needed services on demand.

However, pervasive environments may be structured in different ways. They can range from wired networks to completely wireless ones, where communication among the devices is performed in an ad hoc way. Such a characteristic indicates that the way services are provisioned in a pervasive computing environment should fit in its organization, in order to enhance the access to the services available.

Considering the above discussion, in this article we provide a review on service provision and its applicability in pervasive computing. More precisely, we will list the existing service provision approaches and discuss the characteristics and problems associated with each one, as well as their usage in pervasive computing environments. We start by providing introductory concepts of service-oriented and pervasive computing, respectively in the service-oriented computing and pervasive computing sections. Next, we present the service provision techniques available and how they can be applied for pervasive computing environments. The main current solutions within this scope will be introduced in the service oriented technologies section. Some of the future trends associated with research for service provision in pervasive computing environments will be presented in the future research trends section. Finally, in the conclusions section we present the conclusions of this article.

**SERVICE-ORIENTED COMPUTING**

The service-oriented computing (SOC) paradigm has been considered as the next step in distributed computing (Papazoglou, 2003). In a general way, this paradigm can be viewed as the development of applications through the runtime integration of software pieces named of services (McGovern, Tyagi, Stevens, & Mathew, 2003). In this process,
three elements are involved: defining what is known as a service-oriented architecture (SOA), a service client, a service provider, and a service registry. The former is the one who wishes to use a service. Conversely, service providers are those which offer services for potential clients. Finally, the service registry is where providers advertise or announce their services (through service advertisements), enabling clients to dynamically discover them. By dynamic, we mean that clients are capable of discovering services at runtime, thus providing a high degree of flexibility for applications. Once clients have discovered a service, they are able to bind to it; that is, to create a link with the service, in order to use it (through a proxy to the real service). This process of advertising, discovering, binding, and using a service is illustrated in Figure 1.

In open environments, the dynamic discovery of services implies that they can be used by heterogeneous clients. Within this scope, heterogeneity is concerned with features like the operating system running in each client and the hardware platform it has been built on. As a consequence of such heterogeneity, for enabling an application to flexibly integrate services, they should present the following features (Papazoglou, 2003):

- **Loose Coupling**: A service must not require from the clients any knowledge about its internal implementation.
- **Implementation Neutrality**: The usage of services must not rely on any specific programming language, operating system, or hardware platform.
- **Dynamically Discoverable**: Services should be discovered at runtime.

**PERVASIVE COMPUTING**

The field of pervasive computing has its origins at the Xerox Palo Alto Research Center. The pioneer work that has been led there has culminated in the novel article of Mark Weiser in 1991 (Weiser, 1991), where he describes the first ideas of pervasive computing. Weiser’s vision is at the same time revolutionary and simple: a world where computing is embedded in everyday objects, like cars, televisions, and air conditionings, all seamlessly integrated into our lives and performing tasks for us (Turban, Rainer, & Potter, 2005). When Weiser talked about seamless integration, he meant that applications running in these objects should act proactively on our behalf. They should, for
example, present us with relevant information, based on what we want/need and the resources (e.g., a printer) available in the environment we are immersed.

**SERVICE PROVISION APPROACHES IN PERVERSIVE COMPUTING**

When provisioning services in a pervasive environment, one aspect to be considered is the way it is organized; that is, whether the environment is based on a wired network infrastructure, whether it is formed in an *ad hoc* way, or both. This is necessary for dealing with the particularities of each environment, and within this scope, we can say that there are two major ways of performing service provision (Nickull, 2005): the *push-based* and the *pull-based* approach. In the next sections we will outline each of these approaches as well as describe how they fit into pervasive computing environments.

**Push-Based Service Provision**

In this approach, a provider advertises its services directly to potential clients. In other words, it sends service advertisements to all network hosts, whether they are interested on the service or not. Such advertisements, when received by a host, will be kept in a local service registry. Therefore, once a client wants to discover some service, it will then look up in such a registry for the services that match its needs. An example of the push-based service provision is illustrated in Figure 2. Note that the provider, host A, sends the advertisement of a service directly to hosts B and C, as illustrated in Step 1. When this advertisement is received, it will be stored on a local service registry at each host (Step 2). Then, once a host, in our example host C, wants to discover a service, it then inquires this registry, as illustrated in Step 3. Finally, considering that a relevant service has been found, it is possible to ask its provider (host A) for a proxy to the service (Step 4), enabling host C to use it.

Using this approach, one major problem to be pointed out is about the validity of the service advertisements. It is concerned with the fact that a service provider can leave the network, but the advertisements associated with its services can still be available. One approach which could be used for solving this problem is to require the provider to explicitly notify the network hosts about its leaving, and consequently its services will be no longer available. The problem is that it is not always possible to do that. For example, if the provider is a mobile device, it may be suddenly run out of energy. To deal with this, providers could be aware of the energy level of the device, in order to notify the network hosts that within some minutes it may not be accessible anymore. However, other factors can be involved in the leaving of a provider from the network. It can be just turned off by its user, or leave the network coverage area. Keeping track of all these factors is a task that certainly overloads the provider. A more reasonable solution would be requiring both providers and clients to cooperate for renewing the service advertisement. Therefore, as long as the advertisements are renewed, it is possible, but not guaranteed, that the service is available. On the other hand, when the advertisement has not been renewed within a time interval, then the service is probable, but also not guaranteed, to be unavailable, either because its provider has left the network or because the service has been unadvertised.

One interesting point to notice is that the push-based service provision does not require any physical infrastructure. This means that such an approach is well suited in decentralized and/or infrastructure-less pervasive environments. One problem, in the scope of pervasive computing, is that the advertisement task can consume a lot of bandwidth if many devices are provisioning services in the environment. Therefore, in envi-
environments with very limited wireless links this is certainly a major problem. On the other hand, as services are searched locally, the discovery process does not involve costs of communication.

Pull-Based Service Provision

In the pull-based approach, in order to discover services clients must inquiry remote registries for the needed services. This can be performed in two ways; either using centralized or distributed registries.

Centralized Provision

The centralized service provision consists in scattering service registries in specific servers (i.e., registry servers) of the network. Therefore, for advertising a service, the provider must initially find which of these servers are available in the network. After that, it has to determine in which of them the service will be advertised (instead, the provider could advertise the service in all the available servers). When a client wants to discover services, it must also find the registry servers available in the network, and then discover the services advertised in them. It is important to notice that, once the registry servers are found, unless they become unreachable, clients and providers do not need to discover them anymore. Jini and Web Services are some of the current technologies that support centralized service provision. In Figure 3 we illustrate an example of such an approach. In such a figure, services are advertised by hosts A and B (Step 1), in a single registry server, host C (we are considering that the clients have already found the registry server). After that, each advertisement is stored in the service registry maintained by host C (Step 2). Also considering that host D has already found

Figure 2. Example of a push-based service provision
the registry server, it is then able to inquiry such server for the advertised services (Step 3). When a relevant service is found (Step 4), host D can interact with its provider, in this case host A, to retrieve the proxy for the service (Step 5).

A problem with this approach is that, if all these servers are off the network, services can not be discovered, even when their providers are available. In these cases a possible solution could be the election of new servers from the moment that is detected that the others are no longer available. Furthermore, the centralized service provision raises the same problem of the pull-based one concerned with the validity of the service advertisements. In this way, the same, or at least similar, solutions can be applied here.

As the centralized service provision requires the existence of registry servers, it is not well suited for highly dynamic pervasive environments. In these cases, as nodes join and leave the environment all the time, there would be too many changes in the current registry servers, which would in turn degrade the provisioning of services. On the other hand, this approach is very useful for environments equipped with wired network. In such environments, services can be deployed in the wired network and thus be accessed by mobile clients through wireless links. In environments populated with lots of mobile clients, this is certainly a good choice, as the bandwidth available in the wired network could support a great number of accesses.
Distributed Provision

In the distributed service provision, services are advertised in registries located in each host. Undoubtedly, in this approach the advertising task is easier to be performed than in the other ones, as it does not involve sending advertisements to central servers or directly to the other hosts. However, service discovery is more complicated, as it must be performed by inquiring each available host for the needed services. As no centralizer hosts are necessary for advertising services, discovery is possible whenever a client and a provider are present in the network. An example of the distributed service provision approach is illustrated in Figure 4. Initially, each host advertises its services (Step 1). Once a client needs to perform service discovery, in our example host A, it asks every host in the network for the needed service (Step 2). It is important to note the possibility of redirecting the service discovery request to hosts that are not reachable from the client. In Figure 4 this is performed by host B when it redirects the request of host A to C. When a host has a service matching the client’s needs, it sends a notification (Step 3). From this notification, the client can then retrieve a proxy to the service (Step 4).

The major problem with this approach is associated with the protocols for performing service discovery. As any node in the network is a potential service provider, the discovery protocol must be well designed, in order to cover all hosts of the network. If any host is missing in the discovery process, it is possible that a relevant service may not be found. In \textit{ad hoc} pervasive environments, one possible solution to this problem is first to dis-

\textbf{Figure 4. Example of a distributed service provision}
cover the hosts in the vicinity, and then to retrieve
the relevant services they provide. However this
solution only performs well in small networks,
where the available hosts can be discovered from
any other one. Another point to be considered is
about the network congestion that such service
discovery protocols can cause. As the search
should include all hosts in the network, the protocol
must apply techniques for avoiding flooding the
network. Obviously, this is not a serious problem
in wired networks, but considering the wireless
ones, it must be strictly taken into account. A
good usage scenario of the distributed provision
approach is a decentralized pervasive environ-
ment where the edge of the network is formed by
mobile clients and its core is populated by service
providers connected through a wired network.

SERVICES ORIENTED
TECHNOLOGIES

In this section we present the main technologies
related to the provision of services in pervasive
computing environments.

Universal Plug and Play (UPnP)

The Universal Plug and Play (Richard, 2000)
is an open architecture, which uses standard
Internet protocols for pervasive peer-to-peer
network connectivity (http://www.upnp.org). The
UPnP protocol defines a set of steps, addressing,
discovery, description, control, eventing, and
presenting, which enables the automatic network
configuration and service provision. Through the
addressing, devices get their network address,
which is performed by a dynamic host con-
figuration protocol (DHCP). The discovery step
consists of notifying the other hosts, through the
push-based approach, about the services, and em-
bedded devices, that a joining host provides. The
discovery can also be performed in a distributed
cap-based fashion. The next step, description,
is about the description of a device, stored as an
XML document. In such a document, it is kept,
among other information, the description of the
services that the device provides. Therefore, by
discovering a device, it is possible to retrieve the
services it provides, and then, through the control
step, invoke their actions. Changes in a service
can be notified to interested devices through the
eventing step. Finally, through the presenting step,
it is possible to load a specific URL, specified in
the device description, in order to display a user
interface for controlling a device.

Jini

Jini is a service-oriented Java technology based on
a centralized pull-based approach (Waldo, 1999).
Therefore, service advertisements are stored in
central servers, which are named lookup servers.
Jini uses the RMI (http://java.sun.com/products/
jdk/rmi - Remote Method Invocation) protocol
for all interactions involved in the advertisement,
discovery, and invocation of services. When a
client discovers and binds to a service, it is in-
corporated to the client by downloading the code
of a proxy to the required service, named remote
control object.

The Jini platform uses the concept of lease
for controlling the access to the services. A lease
is a sort of warrant that a client has for using a
service during a specific period of time. When
the lease expires the client needs to renew it
with the provider if it wishes to continue using
the service.

Bluetooth

Bluetooth is a standard for wireless communica-
tion among small devices within short distances
(Johansson, Kazantzidis, Kapoor, & Gerla, 2001),
defining higher-level protocols for both host and
service discovery (http://www.bluetooth.org). The
discovery of services in the Bluetooth standard is
defined by the service discovery protocol (SDP),
which enables to enumerate the devices in the vicinity and retrieve the services they provide.

Bluetooth uses a distributed pull-based approach for service advertising and discovery. To this end, each device maintains its own service discovery database (SDDB), which is a registry where its services are advertised. Therefore, a Bluetooth device performs service discovery by querying the SDDBs of the devices around. These advertising and discovery processes are illustrated in Figure 5. Notice that, initially, all devices advertise their services on their respective SDDBs (1). Next, a client searches for all the Bluetooth devices on the range of its wireless interface (2). For each device found, the client sends a query about the availability of an interested service (3). The devices answer these queries by informing whether they offer the needed service or not (4). Once localized a device providing the desired service, the client can connect directly to such device and finally use the service (5).

**FUTURE RESEARCH TRENDS**

Although the first service-oriented pervasive computing solutions have been developed, much work has to be done yet. For example, the matching of the user’s needs and the services’ functionalities should be enhanced to improve the interaction of the user with the pervasive application. Still, problems remain in the context of service continuity. Solutions to this problem would enable the user to use a service continuously, as he/she walks through different environments. This is important because, sometimes, the service a client was using is not available in the new environment, and thus, some mechanism should allow it to use a similar one without, or at least with a minimum, of interruption.

These, and possibly other problems related to the provision of services in pervasive environments, must certainly be completely solved so that we can enjoy the full potential of merging service-oriented and pervasive computing.
CONCLUSION

The service-oriented paradigm has proved to be an important element in pervasive computing systems, in order to provide anytime and anywhere access to services. Its dynamic binding feature enables to build applications powered with on-demand extensibility and adaptability, two important elements of any pervasive system.

Given this trend, in this chapter we have tried to present an overview of service provision in pervasive computing environments. More precisely, we have showed an introduction to the main characteristics, challenges, and solutions concerning the way that services are advertised, discovered, and used in pervasive environments. Although we presented concepts at an introductory level, we believe they may serve as a good source of knowledge, helping both students and researchers involved with these fields.

Chapter 1.22
Preparing Participants for Computer Mediated Communication

Robert Jordan
U.S. Bureau of Labor Statistics, USA

ABSTRACT

Computer mediated communication (CMC) provides a way of incorporating participant interaction into online environments. Use of such features as discussion forums and chats enhance collaborative work and learning. For many, however, CMC may be an unfamiliar medium. To ensure a successful CMC event, it is essential to adequately prepare participants for CMC. A proposed four step model prepares participants for CMC. The four steps include conducting a needs and population analysis, providing an orientation before the event and shortly after the event begins, and providing continuing support.

INTRODUCTION

Computer mediated communication (CMC) provides interaction during online events, whether synchronous or asynchronous. The moderator-to-participant and participant-to-participant interaction present in CMC offers participants an environment that closely replicates face-to-face interaction with which they may be more comfortable. The advantages of CMC are diminished if participants are not adequately prepared for its deployment and use. In addition to examining why participants may be uncomfortable with CMC-based interaction, this paper proposes several strategies for effectively preparing participants for CMC. These strategies are based on experiences delivering online training across the country to an audience that was unfamiliar with CMC-based interaction.

BACKGROUND

Moore and Kearsley (2005) cite one common misconception that participants new to online learning hold is that learning online is less demanding than face-to-face learning. In fact, the
Preparing Participants for Computer Mediated Communication

opposite is generally true. Effective participation in CMC environments requires participants to be highly motivated and less passive than what may be possible in a face-to-face environment. They must be prepared for what they will experience in CMC. If not addressed at the outset, this misconception may result in participants falling behind and never becoming comfortable and engaged in CMC.

Sherry (2000) cites Fishman in highlighting several potential constraints on CMC-based learning. These constraints include the participant’s lack of experience with using computers, cultural influences, and apprehension about electronic communication (Sherry, 2000). Hiltz and Wellman (1997) describe a sense of pressure on new CMC participants and an uncomfortable feeling of being lost that many of them experience after they first venture into a CMC environment. In addition, new participants are often apprehensive about using technology to communicate and may be more guarded in what they post in discussion forums or chat rooms when compared to what they might otherwise communicate in a face-to-face environment (Puetz, 2000; Sherry, 2000). They may need time to find their online voice (Sherry, 2000). Finding one’s own voice, knowing what to say and when to interject it in an online environment is critical in CMC and the earlier that participants are comfortable with this, the more successful the CMC event will likely be. As features such as instant text messaging and chat are more widely incorporated in everyday life, participants should be more comfortable with CMC.

Many universities incorporate instant messaging in their online education. One such example was the use of MSN Messenger in a mathematics course at the University of Southern Queensland (Loch & McDonald, 2007). Students in the mathematics course were comfortable using many of the features of the instant messaging application, including the electronic ink feature (Loch & McDonald, 2007). Increased organizational use of instant messaging and its improving functionality will likely result in its increased use in CMC events.

While a lack of comfort in communicating online is the primary challenge for CMC, surveys have indicated several other factors that may result in discomfort with CMC (Lewis & Romiszowski, 1996). Some participants are uncomfortable with the nature of asynchronous communication and may be frustrated with the time lags between postings and responses in online discussion forums (Lewis & Romiszowski, 1996; Sherry, 2000). For some participants, the delay in back-and-forth communication lacks the spontaneity and directness of face-to-face communication. Some participants are reluctant to express candid personal views in discussion forums or chats, since they fear that their postings can easily be printed out or saved (Lewis & Romiszowski, 1996). Apprehension about leaving a “paper trail” is understandable. What might be said and forgotten in a face-to-face environment may be misinterpreted and taken out of context in a written form. Participants may become frustrated when others post comments in discussion forums and in chat sessions that reflect their own ideas before they get a chance to comment (Lewis & Romiszowski, 1996). In a face-to-face environment, participants may be able to better gauge when they should interject comments. Those who post late in discussion environments are at a disadvantage in expressing what might appear to others to be original ideas. This situation occurs in face-to-face environments as well, as anyone who is familiar with the overeager “hand raiser” can attest. It might seem to be more clearly evident in CMC due to the text-based method of communicating. The give-and-take of face-to-face verbal interplay is replaced with a written record of who stated what and when.

Technology continues to evolve and may mitigate some of these challenges. For instance, some
discussion board applications now allow users to easily post audio or even video postings and responses, thus reducing the emphasis on text-based communication. In addition, most CMC tools allow participants to “subscribe” to discussion board forums so they can receive instant updates of activity on the boards either via e-mail or really simple syndication (RSS) site feeds.

Another concern expressed about CMC is that online discussion board or chat postings, made without the benefit of non-verbal visual cues, may be misinterpreted and more contentious than what might otherwise occur in a face-to-face environment. There are social communication mores that are evolving in online environments, such as the wider usage of emoticons, which are alleviating this concern. Many available Web conferencing and other CMC tools now formally incorporate the use of emoticons as non-verbal cues in communication.

Moore and Kearsley (2005) cite four reasons for participant anxiety in online environments.

1. Participants are apprehensive about CMC, particularly those new to it
2. Some participants express concern about the quality of online events, such as courses
3. Access to technology-based resources necessary for participating may be a challenge for some participants
4. Some participants worry about the personal resources and expenditures that are required to fully participate in CMC

Technological challenges remain. Participants who can not easily access CMC applications are at an immediate disadvantage from which they may never fully recover. For example, some tools require downloadable plug-ins and players, which may pose security problems if the participant is using a computer supplied by their workplace or public library. Bandwidth availability must be considered as well if the tools used are rich in multimedia. As use of Web-based applications expands, these challenges should diminish. For the present, however, developers of CMC events are wise to assess these potential challenges.

STRATEGIES FOR INCREASING PARTICIPANT COMFORT WITH CMC

Lorraine Sherry (2000) suggests five keys to adoption of CMC by participants:

1. They must believe there is a clear benefit to engaging in CMC
2. They must overcome any fear they have of technology
3. They must feel social and cultural compatibility in the CMC environment
4. They must feel comfortable with the CMC event’s “scaffolding”
5. They must find their online voice

Sherry (2000) cites Engestrom in highlighting the importance of cultural effects. Ultimately, CMC is a social culture that includes those who participate in it, the online tools and conventions that foster it, and the tangible and intangible results that accrue from it (Sherry, 2000). For CMC to be successful, participants must believe that they have a stake in the process and feel a connection with fellow participants as could exist in a face-to-face interaction. As online interaction expands, sustaining online communities should become easier, but resistance remains strong among those who view online communities as remote or impersonal.

There are several strategies for preparing participants for online participation. Sherry (2000) cites Wilson and Ryder who suggest several strategies. These include demonstrating the technology prior to a CMC event, providing online consultation with participants, employ-
Preparing Participants for Computer Mediated Communication

Preparation for moderated discussion forums, establishing a model for “netiquette,” and providing desktop aids and tip sheets for participants (Chou, 2001; Sherry, 2000). Such tactics reassure CMC participants and reinforce the idea that they are part of a larger community.

Gilly Salmon (2003) recommends an online orientation session highlighting tips for communicating before online courses using CMC. Orientation might take the form of a face-to-face demonstration of how CMC works or in a Web conference, in which the system and tools to be used in the CMC event can be demonstrated and “remote control” passed to participants so they can gain comfort in using the tools. In addition, moderators might decide to incorporate features such as online seminars, virtual office hours, and participant journals as ways to make participants more comfortable with CMC (Chou, 2001). Including chat sessions creates an interactive environment that more closely resembles face-to-face interaction. Emerging Web conferencing tools provide a convenient and effective way to build participant confidence in CMC technology before they enter a CMC event. Many of the Web conferencing tools currently available provide polling tools that allow moderators to assess the feelings of participants toward CMC before the event occurs and allow the moderator to make adjustments if needed. Web conferencing applications, such as WebEx, Adobe Connect, Live Meeting, or Centra among others, are generally more effective than the chat tools currently often integrated in asynchronous online environments.

Developers of CMC-based events should integrate a variety of learning styles into their events by providing for a variety of participant activities (Salmon, 2003). The advantage to incorporating various learning styles is that it promotes the concept that there is something to accommodate all participants in the CMC environment. An auditory learner, for example, might appreciate an audio or video clip introducing the event. A visual learner might appreciate well-designed tables or simulations and screen captures with voice-over narration. Tactile learners might find online collaborative exercises and projects engaging. In any CMC event, moderators should strive to keep the entire audience interested in not only the communication but also in the content on the site. An interested participant is more inclined to contribute.

CMC moderators should engage new participants quickly to make them comfortable with communicating online. This particularly is true for inexperienced participants, especially those who may be skeptical or fearful about participating in CMC. The optimal solution is that participants are comfortable with logging into an event. Preparation should begin well before the event and continue as the event unfolds. The next section will describe a specific plan for preparing participants for CMC, with an emphasis on preparing the most inexperienced participants and increasing their comfort with what will be expected of them in a CMC environment.

A MODEL FOR PREPARING PARTICIPANTS FOR CMC

A four-step model assists in preparing participants for CMC events. The four steps are as follows:

1. Analysis of needs and population
2. Participant CMC orientation (before event)
3. Online introduction to CMC
4. Continuing support

Analysis of Needs and Population

As in many development processes, the analysis phase is essential. Developers must analyze the needs of the specific population that will be served to determine the appropriate levels of the
Preparing Participants for Computer Mediated Communication

orientation and continuing support necessary to ensure success of the CMC event. Performing a thorough analysis in advance of the event will provide information to the developers that they can use in building their event. The model for providing analysis discussed here is based on two models that are often incorporated in traditional instructional system design models:

1. Needs assessment
2. Population analysis

Needs assessment reveals the attitudes of the targeted audience as well as their needs (Hodell, 2000). For online training using CMC, this step would likely be undertaken as a part of the instructional systems design process, but is should be completed for any significant CMC event. While the focus of the needs analysis will often be focused more on the subject matter content that will be discussed during the event, the information is of value in assessing how CMC can be effectively used to deliver the subject matter. For instance, if the needs assessment reveals a desire for participant and moderator interaction revolving around specific topic areas, the event can be designed with discussion boards or synchronous chat sessions. What developers should be looking to obtain from the needs analysis is how CMC will be employed during the event to meet the interests of the audience and build upon their needs.

Population analysis assesses the targeted audience (Hodell, 2000; Puetz, 2000). This is important to the CMC developer and moderator in that it will determine the direction of the remaining steps in the four-step model highlighted above. Questions in the population analysis survey should be designed to assess the comfort level of the targeted audience with the methods commonly used in CMC (Puetz, 2000). Hodell (2000) recommends building a population profile of the targeted audience from the results of the survey. Surveys might include the following questions:

1. How much time is spent online during an average work week?
2. How much time is spent online outside of work during an average week?
3. Are CMC features such as instant messaging, chat rooms, and discussion boards commonly used in the audience’s workplace?
4. How familiar and comfortable is the targeted audience with these features and do they use them frequently at home and in the workplace?
5. What is the audience’s perception of online environments versus face-to-face environments?

Taken together, the needs assessment and population analysis provide an important first step in the process of preparing participants for CMC. Without completing the analysis step, a CMC event developer will be at a disadvantage.

Participant CMC Orientation (Before Event)

The level of participant orientation necessary before a CMC event should be determined once the results of the assessment in step one are complete. Orientation should begin one to two weeks before the event. The objective of the orientation is to provide participants with a clear idea of what to expect when they first logon to the event and familiarize them with the features that they will be expected to use to communicate with fellow participants.

Two orientation methods are suggested:

1. Asynchronous and synchronous online orientation
2. Desk aids

Online orientation may be either asynchronous or synchronous. Asynchronous orientation provides participants with a virtual tour of the features of the technology that will be employed
Preparing Participants for Computer Mediated Communication

during the event. The CMC technology that will be used in the event may also have a tutorial that can be provided to participants. There are many screen capture applications available in which screen actions are recorded with or without voice-over narration. Recorded actions should include a demonstration of the features that will be used during the event.

Synchronous orientations sessions provide the additional benefit of participant interaction. Commercial Web conferencing tools allow moderators to demonstrate the features of the system being used to participants. Web conferencing also allows for participant questions and reactions which may be useful in refining the event before it occurs.

Desk aids that participants can refer to throughout the course are also invaluable. Participants can refer to the desk aid until they become familiar with the features of the CMC system that will be used in the event. The desk aid might incorporate screen captures that show participants how the screens look when they log into the CMC event. Other functions such as logging in, posting in discussion forums, and participating in chat sessions can be included in the desk aid. Policies and restrictions may be included in the desk aid as well. The desk aid may be distributed in electronic format so participants can print it out as needed.

**Online Introduction to CMC**

Participant preparation models exist, including a five-step model for online learning developed by Gilly Salmon (2003). Salmon’s model is applied as the CMC event begins. The first two steps of Salmon’s five-step model directly relate to initial orientation. These two steps are access and motivation and online socialization (Salmon, 2003). In the first week, moderators must ensure that participants access the system successfully. If there are challenges initially in accessing the event, participants may drop out of the event or never become fully engaged with the event. This is particularly true for those participants who are not comfortable with technology or the demands that are made of CMC participants. To ensure full participant access, moderators should monitor participation and contact participants who do not log in shortly after the event begins. Moderators should also provide an e-mail address or a telephone number so participants can contact them if they experience difficulties accessing the event.

Online socialization early in the event is desirable. It is suggested that a discussion forum be established for participant introductions. The moderator should encourage participants to post early during the event. Participants should provide information on themselves, their reasons for participating in the event, and perhaps post a photograph. Building online socialization early in the event will promote communication throughout the event.

Another suggestion for early in the event is to provide participants with information on proper techniques for communicating in an online environment. Articles on “netiquette” may be attached or linked to from within the CMC Web site for participant access.

**Continuing Support**

Participants should be supported throughout the course of the event. It is suggested that a discussion forum be established for questions that the participants might have. Moderators should be vigilant in monitoring participation and be prepared to intervene if participants fail to contribute. It is possible that a lack of participation may indicate that participants are experiencing technical or other difficulties.

**CASE STUDY**

The techniques described above were used in delivering an online training based on CMC.
that was delivered over a four week period. The application used for this training was an open source courseware management system called the modular object oriented developmental learning environment, or Moodle. Moodle provides functions such as discussion forums and chat rooms commonly used in CMC. Well before the development team selected Moodle as the tool to deliver the training, work had begun to prepare participants for CMC.

**Analysis of Needs and Population**

Analysis of the population of potential learners and their needs began before the training was set to begin. The population was comprised of approximately 170 participants from nearly every U.S. state, the District of Columbia, the Virgin Islands, and Puerto Rico. A survey was developed to assess the readiness of this population for CMC and their needs, with a focus on what features of CMC they wanted to see included in the online training.

The survey showed the training developers that the majority of survey respondents frequently used the Internet in their work and were comfortable with computer-based technology. In addition, a number of the respondents had participated in online learning events with CMC features. The respondents of the survey indicated a definite interest in interaction with online moderators as well as with fellow learners.

The conclusion from this front-end analysis was that the population was comfortable with using the Internet and had some experience with online learning and CMC, but by no means had mastered the functions of CMC. The audience did express interest in CMC features that would enable interaction with the course moderators and fellow participants. These results assisted the online training developers in approaching the orientation.

**Participant CMC Orientation (Before Event)**

A week before the event began, participants were provided with a training plan and an orientation desk aid. The desk aid covered navigating to the training Web site, establishing a Moodle account, and signing into a specific section of the training. Also included was information on participating in discussion forums and chat sessions. Screen captures from the Moodle site with detailed explanations were included in the desk aid. Web conferencing might have been used as well, if one had been available to the course developers.

**Online Introduction to CMC**

In the first week’s activity, participants were provided a discussion forum entitled “Ask the Moderators,” where they were encouraged to ask questions related to the course. Moodle incorporates an internal messaging system in which participants sent direct messages to the event moderators. The moderators’ work e-mail addresses were also provided. Finally, a link to a Wikipedia entry on “netiquette” was posted in the first week’s activities.

As a result of the preparation the great majority of participants experienced no difficulty logging into the Moodle Web site. In the few instances where participants experienced difficulties logging in, the difficulties were resolved quickly, in part because they knew how to quickly contact the moderators. Participants indicated in the evaluation sheets that the desk aid helped them to log in and know what to do once they were in the Web site. They also appreciated knowing the moderators could be contacted easily from within the Web site.

**Continuing Support**

The “Ask the Moderators” discussion forum was included in all four weeks of activities. The mod-
Preparing Participants for Computer Mediated Communication

ERATORS made use of a Moodle feature referred to as a “new forum” discussion board to post reminders and tips for enhancing the experience.

FUTURE TRENDS

As more organizations look to contain costs, it is expected that even more of them will turn to some form of CMC. As CMC draws more participants, there is potential for problems if these new users are not fully prepared for what is required in a CMC environment. With more people using Internet technology, including CMC, it can be expected that less intensive preparation may be required in the future. The nature of the preparation may also change with the evolution of technology and in the way CMC is delivered. For instance, audio-based discussion boards now exist allowing participants to record their postings and responses to posts, rather than responding by typing text.

Another future trend is the emergence of more sophisticated modes of online communication. One popular social online community is called Second Life, a virtual reality gaming environment that allows participants to create alternate identities and lifestyles through avatars. Community members can buy and sell virtual products, services, and even real estate using virtual dollars that can be exchanged for real money (Newitz, 2006). The success of these virtual communities serves as a model for creating and sustaining an online community. Companies such as Wal-Mart, American Express, and Intel have been studying interaction in Second Life in conjunction with their corporate training objectives (Newitz, 2006). Ohio University has been incorporating Second Life into its formal online learning programs (Dewitt, 2007). Virtual communities such as Second Life provide a more life-like form of interaction than what is generally seen today in CMC.

The closer developers can get to replicating face-to-face interaction, the more likely that CMC will be accepted by a broader audience. Virtual reality applications, such as those provided in Second Life, provide a glimpse into the future of CMC can become.

CONCLUSION

Organizations are turning to CMC as a way of meeting, collaborating, and learning. More people are being introduced to CMC, including users who are unfamiliar with the style of communication or the technology involved. Participant acceptance of CMC will grow if they are prepared for what is encountered in a CMC environment.

A four-step process may be employed to prepare participants for CMC. These steps include conducting a needs and population analysis on the target audience, providing a participant orientation before the CMC event begins and during the first week, and providing continuing support throughout the event. A systematic process ensures that CMC developers and moderators will understand their audience’s strengths and weaknesses and will enable them to develop an effective deployment strategy. Communication techniques found in CMC offer participants an environment that more closely replicates face-to-face interaction with which they may be most comfortable. Preparing participants for CMC is critical in making participants comfortable with communicating online.

REFERENCES

Preparing Participants for Computer Mediated Communication

KEY TERMS

Asynchronous: Online communication that does occur at the same time.

Avatar: A computer-generated representation of an online participant commonly found in virtual reality environments.

Computer Mediated Communication (CMC): Design that incorporates synchronous and asynchronous online communication that promotes interaction among participants. Such features include discussion forums and online chat features.

Needs Assessment: An analysis of the needs and desires of a target audience. Methods of conducting a needs assessment include survey questionnaires, focus groups, and personal interviews.

Open Source: Programs that are developed with an open license and distributed without cost. Upgrades to programs and support are often provided by the user community.

Population Analysis: An analysis of a targeted audience focusing on its attributes, abilities, and feelings.

Synchronous: Online communication that occurs among participants simultaneously.

This work was previously published in the Handbook of Research on Computer Mediated Communication, edited by S. Kelsey and K. St.Amant, pp. 25-33, copyright 2008 by Information Science Reference, formerly known as Idea Group Reference (an imprint of IGI Global).
Chapter 1.23

Computer–Mediated Communication Research

J. D. Wallace
Lubbock Christian University, USA

ABSTRACT

This chapter asks “What is meant by computer-mediated communication research?” Numerous databases were examined concerning business, education, psychology, sociology, and social sciences from 1966 through 2005. A survey of the literature produced close to two thousand scholarly journal articles, and bibliometric techniques were used to establish core areas. Specifically, journals, authors, and concepts were identified. Then, more prevalent features within the dataset were targeted, and a fine-grained analysis was conducted on research-affiliated terms and concepts clustering around those terms. What was found was an area of scholarly communication, heavily popularized in education-related journals. Likewise, topics under investigation tended to be education and Internet affiliated. The distribution of first authors was overwhelming populated by one time authorship. The most prominent research methodology emerging was case studies. Other specific research methodologies tended to be textually related, such as content and discourse analysis. This study was significant for two reasons. First, it documented CMC’s literature historical emergence through a longitudinal analysis. Second, it identified descriptive boundaries concerning authors, journals, and concepts that were prevalent in the literature.

INTRODUCTION

Computer-mediated communication (CMC) involves a wide number of characteristics involving human communication. It also includes systems, methods, and techniques that are typical of online environments. Therefore, one would rightfully expect definitional difficulties both technological and methodological. Wallace (1999) extensively surveyed the literature concerning CMC and found relatively few definitions. While differences abounded in the definitions found, the one constant was the use of the computer as an intermediary device. The centrality of the computer and communication layers human characteristics and technological issues.
Levinson (1990) suggests that in order to understand a device or a technique, not only should we take a microscopic view through research and examination, but we should also take a more macroscopic view. A survey of the scholarly communication might help provide a different perspective. Hopefully, it would reveal some of the larger areas of inquiry concerning online research in general, and computer-mediated communication specifically. This macroscopic survey would enable researchers and scholars to more efficiently coordinate their own activities with outlets and concepts that have the most pressing need for their contributions. It has the additional benefit of documenting CMC's developmental features that can be compared with future research or differing methodologies.

Similar to other such studies, the purpose of this chapter is provide an overview of the CMC scholarly literature, and to “identify its component features in providing a tangible means of identification” (Dick & Blazek, 1995, p. 291). Likewise, it is not to determine the magnitude that CMC occupies as a discipline, field, specialty, or subspecialty area. For purposes of literary description, the term “field” is not a cataloguing designate, but rather a convenient moniker under which CMC scholarship resides. CMC is often described in the literature as a field. However, designates of specialty, or subfield are probably more accurate.

Simply put, the statement of the problem is: “what are trends in computer-mediated communication research?” Definitions and descriptions of current literature on the subject reflect views that are selective and often disparate. Rather than revisit debatable definitional issues, an arguably more objective approach will be used as the focus of this inquiry. Specifically, what authors, journals, concepts, and research issues possibly populate the CMC domain?

Certainly, a number of conceptual problems would be introduced with any kind of predictive examination (Hargittai, 2004). Therefore, exploratory and descriptive procedures seem more appropriate than postulating hypotheses. With this in mind, the original question concerning CMC has, as one possible answer, a bibliometric analysis into the nature of the field. Bibliometrics is the “… mathematical and statistical analysis of patterns that arise in the publication and use of documents” (Diodato, 1994, p. ix).

Library and information science have long used bibliometrics for this kind of analysis. They have a body of literature supporting their validity and reliability. Moreover, bibliometric procedures provide the means upon which relationships of theoretical inquiry can be based. Borgman & Rice (1992) state that: “Bibliometric data are particularly useful for studying longitudinal trends in scholarly disciplines because of the massive datasets that can be utilized. Virtually no other method provides as comprehensive coverage of a topic in scholarly communication” (p. 400).

Journal articles appear to be reasonable and available artifacts for identifying this area. This is done for three reasons. First, their affiliation with the bibliometric theory of problematic network analysis provides support for their representation of scholarly activity. (Coutial, 1994; Courtial, Callon, & Sigogneau, 1984). This theory views scholarly communication and literature as a series of problematisations that reflected the underlying intellectual discourse. Journal articles are seen as the primary artifact from which to extract elements of that discourse. Second, analyses of journals do not consume the financial resources inherent in more exhaustive treatments. Third, their online availability makes this current analysis easier to replicate and contrast when used as a benchmark upon subsequent research.

Research questions. One advantage of surveying the field is to let the “field” define itself as it exists in the extant literature. In this regard, almost 40 years of archival data was examined by combining the results of a previous survey (Wallace, 1999) with this 2005 examination. Hopefully, this will offer a more comprehensive look at how CMC
research is viewed through a database analytic lens. As search engines replace annotated bibliographies and other indexical instruments, the nature of the scholarly profile produced through this lens becomes more critical.

In regard to the above literature framework, this chapter poses four research questions concerning the computer-mediated communication research. These questions are general in nature, and align themselves theoretically with artifacts, producers, and research concepts. The conceptual issues are somewhat more complex than general identification and demarcation that led to the creation of a fourth research question. Simply put, the research questions posed are:

- **RQ1:** What are the primary journals of CMC literature, both past and present?
- **RQ2:** Who are the producers of CMC literature, both past and present?
- **RQ3:** What are the CMC concepts being examined in scholarly journals?
- **RQ4:** How do the current research concepts of CMC relate to other topics in the field?

**Research question 1: Journals.** Research question 1 addresses the scholarly journals representing literature concerning computer-mediated communication. Specifically, it will identify these artifacts by the analysis of frequency data and an identification of core journals across several disciplines. Common databases were set up both in the previous and the current study so that frequency and other component features could be identified.

One advantage of using journals over other artifacts, such as citations, is that they are believed to contribute to minimizing threats to validity (Cronin & Overfelt, 1994; Glaenzel & Moed, 2002; Hyland; 2003; Schloegl & Stock, 2004). Citations often go to secondary sources (obfuscating the real influence), and authors often do not hold the opinions that citation patterns attributed to them. Once frequency counts are established, a number of other component features can be derived, such as prolific and core journals. This may provide indicators of publication patterns that can be used to target future scholarship.

**Research question 2: Authors.** Research question 2 looks at producers of CMC’s scholarly communication. It will be addressed by the analysis of frequency data concerning authorship. Frequency of author publication rate will give a glimpse into the most prolific authors, and has been indicative of some of the major theoretical contributions of bibliometrics (Cronin & Overfelt, 1994; Nicholls, 1989; Rice, Chapin, Pressman, Park, & Funkhouser, 1996).

**Research question 3: Concepts.** Research question 3 identifies the more prominent areas of focus in regard to CMC research. It will be addressed through the analysis of indexical key words from the master database. Indexical key words were chosen as concepts because they have demonstrated useful in identifying research trends in other studies (Callon, Courtial, & Laville, 1991; Cambrosio, Limoges, Courtial, & Laville, 1993; Stegmann & Grohmann, 2005). Key words stand for indicators of scholarly problematisations that are being articulated in the literature (Courtial, 1994; Callon et al., 1991)

**Research question 4: Relationship of research concepts.** Research question 4 investigates how the research concepts of CMC relate to topics in the field. It will be addressed through co-word analysis. This is generally done by analyzing the proximity that key words and other concepts have with one another (Diodato, 1994; Larsen & Levine, 2005; Stegmann & Grohmann, 2005).

**METHOD**

In order to produce a literature survey that spans almost 40 years, two studies were combined. A more recent analysis of CMC research extended a previous CMC literature study (Wallace, 1999). The previous study’s data was collected in June
of 1998, for 1997 and prior, utilizing the indexes of ABI/INFORM, ERIC, PsycInfo, Social Science Index, and Sociofile. The more recent study’s data was collected in August of 2005. EBSCO was used as a common vender in the 2005 study. Academic Search Complete, Communication & Mass Media, Business Search Premier, ERIC, PsychInfo, and PsychArticles were selected as databases. The selected databases are considered prominent resources in the areas of business, education, psychology, and the social sciences. Furthermore, these databases are noted for their strong research affiliations, and have an intuitive link with CMC. A key word search of the respective databases was done for the variable “computer-mediated communication..” Both hyphenated and unhyphenated variations of the term “computer-mediated” were used to insure breadth of coverage.

Each of the databases had idiosyncratic characteristics that made identical survey techniques, across all databases, impossible. However, all methodologies adhered to the following guidelines. Databases were examined to see if there were any inherent journal markers that would enable the extraction of journal articles. Books, book reviews, conference papers, and other nonjournal materials were eliminated through either filters or inspection. Extraneous information and fields were eliminated. Documents were then placed into a common file. Procedures were similar for both studies, and a relatively exhaustive description is available in Wallace (1999).

**Data Analysis**

**Journals.** The data file was examined in terms of journal frequency. From this, it could be determined the identity of CMC journals and how they were positioned in terms of the overall literature as defined by this chapter. Subsequently, Bradford-type partitions were derived to identify the core journals.

Bradford partitions are where journals are ranked from most to least prolific in terms of number of articles produced concerning the subject under scrutiny. They are then divided into “zones” that have roughly the same number of articles. Predictably, the journals that produce the most articles have the least number of journals in their zone. The zone that has the least journals is used to identify the “core” journals for a subject area. Bradford recommended the use of three zones (Diodato, 1994). The previous study serendipitously arrived at three zones through a somewhat more complex procedure. These zones had a relatively equal number of journal articles with the core zone containing a relatively few prolific journals. For comparative purposes, the more current study utilized three zones as well.

**Authors.** The 2005 analysis of authors was also restricted by comparative constraints. The previous study used the straight count method of authorship. The straight count method identifies all the first authors from the journal database. Therefore, both studies used straight count to extract authors for analysis.

After authors were extracted from the master database, they were then rank ordered, and standardized. Frequency and cumulative data was then calculated. The CMC authors were then analyzed from an “authors x number of contributions” format.

**Concepts.** Frequency of problematisations overall were calculated and analyzed for segmentation. This is not only critical for this research question, it is imperative for RQ4. Both Hinze’s (1994) “10 journals or more” and Rice et al.’s (1996) “top 200 key words” were considered exemplars in this regard. The decision was made to view the distribution in terms of which kind of demarcation was most efficient while capturing the majority of the distribution. Fifty percent was considered the benchmark on which to base the comparisons. This is an area where the literature distribution must be known to be able choose the more efficient
method. If neither of the previously mentioned methods surpassed the 50% benchmark, then the literature would be deemed too disparate to determine more prominent terms.

Once segmentation was determined, then the core key words were longitudinally examined for their visibility. The previous study examined key words concerning 1997 and prior. The more recent study surveyed the literature from 1997 through 2005. The overlap was intentional as many databases' literatures are not well represented in their last year of analysis (Egghe, 1990). Indicators of this “droop” were present in the previous 1997 survey.

Relationship of research concepts. The above concepts were then scanned for more familiar research affiliated terminology. Terms that appeared methodological, or had the term “research” as a component-attached term were extracted. Establishing relationships was done through cluster analysis. A number of clustering procedures have been used in the analyses of emerging fields. The complete linkage method (furthest neighbor) was considered an appropriate procedure because of its rigor over the single linkage method and its comparability to the previous study (Aldenderfer & Blashfield, 1984; Hinze, 1994, Wallace, 1999). The lack of knowledge of current granularity of findings also makes this procedure well suited. (McCain, 1989; Spasser, 1997). As with other studies, similarity between concepts was measured using a Pearson relation procedure. (e.g., Hinze, 1994; McCain, 1989; Spasser, 1997).

RESULTS

The 1997 CMC study generated 611 unique article references for 1997 and prior. Four hundred and fifty-nine, or about 75%, tended to be education related as indicated by their ERIC affiliation. The current examination started from a more mature 1997 dataset through 2005. It generated 1,326 unique article references. Nine hundred and fifty-three, or about 72%, tended to be education related as indicated by their ERIC affiliation.

The following sections survey journal publication trends for CMC, identify some of the more common terminology within that survey, and then narrow that terminology to research-affiliated terms and concepts clustering around those terms.

Artifacts: Survey of Core Journals

A Bradfordian-type analysis was done both in the more current and the previous study (Table 1). In the 1997 study, journals had to produce six or more articles total to be considered core. In the 2005 study, journals had to produce 11 or more articles.

While roughly the same number of journals were considered core in both studies, only six journals were recognized as core in both studies. These were American Journal of Distance Education, Computers & Education, Computers and Composition, Educational Media International, Information Society, Internet Research, Journal of Educational Computing Research, and TechTrends. A cursory look at journal affiliation reveals that the journals are largely education affiliated. Two notable exceptions are Information Society and Internet Research (see Table 2).

*6 or more articles

*11 or more articles
Productivity of these core journals ranged, in the earlier research, from a high of 16 to a low of 6. The more recent research frequency was appreciably higher ranging from a high of 34 to a minimum threshold level of 11.

To give an idea how this distribution might be comparable to other literature descriptions, in terms of longevity, it was tracked over time. While no journals appeared till 1984, databases were searched in previous years. The most far-ranging search occurred in ERIC, which started in 1966. Records were also examined from ABI/INFORM, Psychlit, Sociofile, and Social Science Index in 1986, 1971, 1971, and 1983, respectively. All databases were producing articles by 1986.

Producers: Survey of Core Authors

Three or more references were used to demarcate core authors in both studies. This formulation has the benefit of fitting within the general contention that authors producing one or two articles have the vast majority of the distribution and should be excluded from consideration (e.g., 94% by Burnham, Shearer, & Wall 1992; 83% by Keenan, 1988). On the other hand, because the production numbers were low in general, using more than three was considered too severe a threshold for the respective studies.

The CMC literature examined was heavily weighted toward authors producing only one article. The early 1997 research had 506 different first authors producing 611 different references. Close to 96% of the authors had one or two publications. They accounted for 87% of the articles produced. The 21 core authors were published in 54 different journals producing 80 different articles. The 2005 survey had a similar distribution, with 1,169 authors producing 1,326 different articles. However, the core authors produced a somewhat smaller 8.5% of the articles. Specifically, there were 31 authors that produced 113 articles in

71 different publications. Only Joe Walther was included in both previous and recent sets of core authors (Table 3).

**Concepts: Survey of Key Terms**

First, to contextualize the conceptual survey concerning CMC, it is useful to understand the scope of the current and previous examination. The previous study had 1,787 unique problematisations (indexical terms) contributing to a total dataset of 6,898 terms. The 2005 study had 2,700 unique problematisations contributing to 12,935 total terms.

The overall datasets were then examined for more dominant concepts. Both Hinze’s and Rice’s methods detailed earlier surpassed the 50% threshold. The previous study used Hinze’s (1994) demarcation, and identified 116 core terms. They accounted for more than 3,684, or 53%, of the total indexical terms mentioned. However, Hinze’s demarcation was primarily used because the previous study’s emphasis was on the totality of the conceptual base. Since the 2005 study was designed specifically to identify research affiliations within that base, Rice et al.’s (1996) more liberal “top 200 terms” was utilized. This accounted for 7,827 or roughly 60% of the entire conceptual set.

While a complete discussion of the core terminology would be unwieldy at best, a physical inspection of the two studies indicated about 30% of the totality of terms is included in the 21 most prominent descriptors. With the admitted concession that computer-mediated communication is the search term predicating the study, these terms still provide an overview of some of the more dominate themes that have emerged in the CMC literature. Table 4 details both studies with the count and rank of terminology that occurred.

Thirteen of the 21 terms appeared in both studies. As would be expected, even with rank differentiation, the more recent study has substantially more contributions. Online systems had the highest overall percentage increase. Decreases were only observed concerning the terms electronic mail and computer networks.

There were eight terms that were not reciprocal (Table 5). The overwhelming number of these fell in the bottom half of the rankings where predominance was not as stable.

</table>
The more exhaustive 2005 analysis was used to identify research-affiliated terms to be inlaid within respective conceptual maps of the two studies. The research-affiliated concepts are listed for both the 1997 and 2005 research studies in Table 6. The highest number of scholarly articles was connected with the term communication research.

The top-ranked term was communication research for the 1997 survey and case studies for the 2005 survey. As would be expected, most concepts were identified at higher levels in the larger, more recent study. However, there were some exceptions to this trend. These included communication research, research methodology, and use studies.

**Conceptual Map of CMC Research Methodologies**

Research question 4 was explored in two ways. First was the identification of prominent problematisations within each of the previously identified research affiliated terms. This was done by setting a somewhat arbitrary four-occurrence threshold that had to be surpassed. What follows is a more lexical description of those relationships. Clearly, terms that are more numerous are not necessarily strongly related, and terms strongly related are not necessarily more numerous. Below are topical areas that were most dominant when the respective research problematisations were used as filters. Because of the magnitude of higher education occurrences, it was included in almost all categories.

**Communication research.** Both studies included higher education, Internet, communication behavior, and group dynamics as areas of foci. Additionally, the 2005 study included interpersonal relationships, student attitudes, and World Wide Web. The 1997 conceptual set was relatively extensive including the following terms:

- Adulthood
- Communication

- Communication Social Aspects
- Computer Applications
- Computer Assisted Instruction
- CMC Systems
- Computer Networks
- Computers
- Decision Making
- Electronic Mail
- Group Decision Making
- Interpersonal Relations
- Organizational Communication
- Social Interaction
- Telecommunications

**Case studies.** Both studies included the indexical terms higher education, Internet, distance education, foreign countries, computer-assisted instruction, and electronic mail. The 2005 study also had World Wide Web, instructional effectiveness, online systems, information technology, college students, literacy, and teacher role. The 1997 study was more writing oriented with computer networks, teaching methods, writing research, student attitudes, collaborative writing, technical writing, and writing instruction.

**Evaluation methods.** Only higher education and computer-assisted instruction appeared prominently in both studies when evaluations methods was used as a filter. However, no other terms, except for the previously mentioned higher education, reached a level of predominance in the 1997 study. The 2005 conceptual set was relatively extensive including the following terms:

- Collaborative learning
- Distance education
- Foreign countries
- Instructional effectiveness
- Interaction
- Internet
- Online systems
- Research methodology
- Student attitudes
- Student evaluation
Comparative analysis. Dominant concepts in both studies included higher education, distance education, and computer-assisted instruction. The 2005 study also had face-to-face communication, interaction, instructional effectiveness, interpersonal communication, nontraditional education, second-language instruction, and second-language learning. The 1997 study had more dominant terms including computer networks, futures of society, teleconferencing, electronic mail, and experimental theoretical.

Discourse analysis. Higher education and interpersonal communication was the only dominant concept in both studies. The 2005 dominant concepts included communication behavior, Internet, language research, second-language instruction, second-language learning, sex differences, and written language. Only two additional terms were dominant in the 1997 study. These were computer-assisted instruction and computer networks.

Educational research. The term educational research did not have sufficient mentions to be considered in the dominant term analysis for the 1997 study. The dominant terms for the 2005 study included higher education, computer-assisted instruction, cooperative learning, distance education, educational technology, Internet, nontraditional education, online systems, and World Wide Web.

Surveys. There were no dominant terms included in both studies other than higher education. The 2005 study featured student attitudes, distance education, and World Wide Web, while the 1997 study featured Internet, computer networks, electronic mail, teleconferencing, information networks, and scholarly communication.

Literature reviews. Distance education was a dominant term in both studies concerning literature reviews. The 2005 study also included community and information technology. The 1997 study additionally had higher education, computer networks, electronic mail, and teleconferencing.

Research. When used as a filter, the singular term, research, did not have sufficient mentions of any terminology to be included in this analysis.

Use studies. Higher education, Internet, and electronic mail were dominant in both studies. Additionally, the 2005 study featured the term World Wide Web. The 1997 study’s dominant concepts were more ranging, including communication thought transfer, computer networks, foreign countries, online systems, tables data, telecommunications, and teleconferencing.

Content analysis. Only higher education was identified for both studies. The only additional dominant term for the 2005 study was Internet. Terms for the 1997 study included electronic mail, interpersonal communication, research needs, and tables data.

Pilot project. There were no dominant mentions of terminology in both studies except for higher education. Additionally, the 2005 study included foreign countries and educational technology. The 1997 study had electronic mail.

Evaluation criteria. Evaluation criteria did not have sufficient enough mentions for dominant term analysis in the 1997 study. The dominant affiliated terms with the 2005 study included higher education, computer-assisted instruction, distance education, Internet, and online systems.

Research methodology. There was no overlap in dominant terms. The 2005 study had distance education and interaction, and the 1997 study had higher education, computer networks, and electronic mail.

The second way research question 4 was explored was to examine strength of affiliation through cluster analysis. This was thought to provide some clues as to which core terms were most closely related to particular research problematisations. Some of the linkages were clearly methodological (Table 7). However, not all terms
were included in both analyses due to the number of occurrences when research term filters were applied. Table 7 identifies clusters of research and affiliated co-occurring terms that appeared in at least one of the studies. Clustered terms tend to be conceptual sets that journal articles focus upon.

Aside from terms that were affiliated across both studies, there were terms that only appeared

*=not enough for 1997 analysis
in the 2005 analysis. These relationship clusters included:

- **Educational Research**: Distance education, nontraditional education, computer-assisted instruction, and educational practices
- **Evaluation Criteria**: Feedback, course content, and course development
- **Pilot Project**: Information services, library services, reference services, user needs, information, and electronic libraries
- **Research**: Communication

### DISCUSSION

This chapter analyzed “what is meant by computer-mediated communication research?” While a number of suitable answers exist for this question, it chose to let the “field” define itself as it exists in the extant literature concerning business, education, psychology, and the social sciences. In this regard, almost 40 years of archival data was surveyed. Wallace’s study of 1997 and prior literature was combined with this 2005 examination to offer a look at how CMC research is viewed through a database analytic lens. Because of the interdisciplinary nature of computer-mediated communication (CMC), a parallel analysis of multiple databases from different perspectives was used (Ingwersen & Christensen, 1997; McLaughlin, 1994; Spasser, 1997). It should be noted that as database sophistication increases regarding education, business, and social life in general, this kind of lens may become more crucial.

The descriptive nature of this study necessarily dictated a balance between rigor and latitude. Several limitations must be considered in this respect. These include generalization, design limitations, and theoretical assumptions. First, operationalization of the domain should clearly impact the use of the findings. Therefore, results from this analysis do not claim to identify characteristics of CMC beyond the domain examined. Second, the selection of cluster analysis over other classifying procedures has a number of inherent limitations. This was considered a necessary condition given the emerging nature of the field. Emergence (or lack of emergence) of clusters will have to be weighed against the nonrandom nature of their partitioning (Aldenderfer & Blashfield, 1984). Third, the design was somewhat restricted in order to have a longitudinal comparison. The above limitations were addressed in the traditional way for descriptive studies. Detailed explanations, including supporting literature, were provided for choices made.

### CONCLUSION

This survey of computer-mediated communication literature revealed three interesting trends. The first trend is a paradoxical turbulence and stability common in literature surveys. This pattern was somewhat present for articles, journals, authors, concepts, and research affiliations. The total articles doubled while the number of core journals remained relatively constant. Both the overall production of articles and the production of core journals increased by 217%. Despite this increase, the number of core journals producing those articles only advanced by 3, from 22 to 25.

The total number of core authors producing more than two articles also had relatively little growth, while there was a virtual turnover in actual author names. Joe Walther was the only author to emerge in both surveys. Core authorship increased by an anemic 30%, from 21 to 31. When considering total articles produced, core author production actually shrank from 13% in the 1997 survey, to 8.5% in the 2005 survey. The top 21 terms in both studies accounted for 30% of the total indexical terms. Eight of those terms were not reciprocal. Most of the unique terms can be attributed to shifts in the more turbulent bottom half of the distribution. However,
telecommunications and information networks were ranked seventh and ninth, respectively, in the 1997 survey, and were not prominent in the 2005 study. One interesting note is that while “World Wide Web” was not a core terminology in the 1997 study, it was identified as the number one emerging concept. In the 2005 survey, it was firmly established as sixth in overall mentions. Communication research and discourse analysis were the only research affiliated terms that fell within the top 21 terms of both surveys.

The majority of the previously identified research terminologies emerged in both studies, but were not related to the same issues. Nine out of the 14 research affiliated terms emerged in both surveys. Serendipitously, the only two terms that were related to each other were also research affiliated. These were content analysis and research methodology. The terms educational research, literature reviews, research, pilot projects, and evaluation criteria were exclusive in that they did not overlap with any of the other dominant research terms.

The second trend is that literature tended to have an online and higher education focus. Five hundred and ten articles were higher-education related. Internet was the second most populous descriptor, with 287 articles. Furthermore, World Wide Web had 176 articles, and online systems had the highest percentage increase with 146 articles. Besides articles, both surveys indicated in excess of 70% of the journals were related to education. Core journals were also highly education and Internet related.

Higher education was also connected with almost all research terminology for both surveys. The only exceptions were the terms research, research methodology, and literature review for the 2005 survey. The 1997 study had higher education absent for educational research, evaluation criteria, and the singular term, research. While the 1997 survey results could be attributed to low production numbers, this was not the case with the 2005 results. Other problematisations with similar production numbers managed to have at least four articles with a higher education affiliation.

The third trend emerged through a post hoc analysis of the 2005 dataset that was not conducted in the 1997 study. Journals were examined to see if they affiliated with any of the dominant research terminology. Most journals were affiliated with a single prominent research term. Eight were affiliated with two terms, and only the journal Internet Research involved three terms that included comparative analysis, evaluation criteria, and use studies. The appendix describes the research affiliation as indicated by key word term, journal that it was published in, and the count of articles in a journal concerning a particular research term.

FUTURE RESEARCH

Clearly, this study detailed CMC research as an area that tended to be education and “Internet” affiliated. Furthermore, the computer-mediated communication literature prominently used a number of textual analysis techniques, such as content and discourse analysis. Noticeably absent were articles focused on possible experimental techniques, ethnographies, and focus groups. This does not mean that these were not tools used in the literature, merely that they were not the focus of the more prominently presented research articles (Schneider & Foot, 2004). Surveys also had a surprisingly diminutive presence. Certainly, there are both specific and extensive treatments of online survey methodology (e.g., Andrews, Nonnecke, & Preece 2003; Katz & Rice, 2002). However, the current examination suggests a need for this and other volumes to specifically localize methodological issues relevant to computer-mediated and online communication.

With the exception of Joe Walther, core authors had completely overturned. While Nicholls concedes the robustness of the straight count, an exhaustive identification of authorship might more
fully answer questions concerning ranking issues, shifting authorships, and omissions (Cronin & Overfelt, 1994; Nicholls, 1989).

One general consideration is that indexed literature does not always reflect the centrality of artifacts and producers. The current analysis focused on work being produced without discrimination in regard to usage. Identification of CMC’s literature usage patterns might provide complementary information to the current study. Furthermore, it would help shed light on whether theoretical or pragmatic issues are driving CMC’s scholarly communication.

Another important consideration is that it is unlikely that people engaged in CMC are overwhelmingly involved in education-related phenomena (Katz & Rice 2002; Papacharissi & Rubin, 2000). If the study of CMC is to more accurately reflect current usage patterns, it should be aggressively broadened in other areas. Conceptual linkages exposed by this analysis are formative at best. Future studies should rigorously examine both the linkages and the conclusions in regard to their longevity and stability.

However, while conceding a number of caveats, this study does identify component features of past and more recent computer-mediated communication research. These resources are readily available online through many library services and outside vendors. Therefore, CMC and “online” researchers can use these features to identify research redundancies, and opportunities to consider, and hopefully more efficiently advance, the scholarship of the field.

REFERENCES

**KEY TERMS**

**Artifacts:** Artifacts are any number of forms of scholarly communication. Conceptually, they could range from working papers to books.

**Bibliographic Coupling:** Bibliographic coupling is where two documents each have citations to one or more of the same publication, but do not have to necessarily cite each other.

**Bibliometrics:** The mathematical and statistical analysis of patterns that arise in the publication and use of documents.

**Bradford Partitions:** These partitions are used in library and information science to establish core journals. The process ranks journals from most to least prolific in terms of number of articles produced concerning a subject. They are then divided into three or more “zones” that have roughly the same number of articles. The zone that has the least journals is used to identify the “core” journals for a subject area.

**CMC:** An acronym standing for computer-mediated communication or computer mediated communication.

**Co-Citation Analyses:** The analysis of journals, articles, or authors that are cited together in an article or articles.

**Concepts:** Concepts are terms or words used by the producers themselves. This could include words in titles and text, or assigned terminology such as key words.

**Core Authors:** Core authors are generally established through a well-articulated benchmark that exceeds two publications.

**Core Concepts:** Core concepts are the relatively few concepts that account for a large amount of problematisations under study.

**Core Journals:** Core journals are generally established through a well-established benchmark such as Bradford partitions.

**Co-Word Analyses:** The analyses of the co-occurrence of two or more words in one document or in different documents.

Chapter 1.24
Computer-Mediated Communication in Virtual Learning Communities

Lisa Link
Flensburg University of Applied Sciences, Germany

Daniela Wagner
University of Hildesheim, Germany

THE MEANING OF CMC

Computer-mediated communication (CMC) can be simply defined as “communication that takes place between human beings via the instrumentality of computers” (Herring, 1996, p. 1) and the technology used in CMC as “media that facilitate the exchange of semantic content, transmitted through telecommunication networks, processed through one or more computers, between individuals and among groups” (Rice, 1984, p. 438). As a concomitant result of the widespread use of computers and the Internet in the curriculum of higher education as well as the inclusion of various forms of online learning, CMC has become a common communication modality in teaching and learning contexts. Although all forms of CMC can be meaningfully integrated into learning contexts, the majority of CMC at present is nevertheless text based and hence the focus of this contribution.

CMC plays a pivotal role in the context of e-learning models in higher education that offer students new forms of learning that would not be possible in a traditional classroom environment. Cooperative and collaborative learning, problem-oriented and project-based learning, as well as authentic learning in which real-world scenarios are simulated, are some examples. In the context of these types of e-learning models, virtual learning communities as well as smaller virtual teams are often an essential component. The learning objectives of these models are manifold, but they generally include offering students the opportunity to acquire, practice and enhance important key competencies required in their future professional work. Hence, communication and media skills as well as the ability to work cooperatively
in a virtual team are just as important as the actual subject matter of the course itself.

**CHARACTERISTICS OF CMC**

CMC can be classified into two major groups: asynchronous and synchronous CMC. The main difference between these two types is temporal: asynchronous CMC is time independent, that is, it does not require that the communication partners be simultaneously online, whereas synchronous CMC takes place in real time or quasi real time, requiring the telepresence of the communication partners. E-mail, mailing lists, and discussion forums are examples of asynchronous forms. Chat rooms and shared whiteboards represent synchronous forms of CMC.

A further classification of CMC is whether it represents a one-to-one (1:1), one-to-many (1:n) or many-to-many (n:n) communication form. Depending on their use, the different types of CMC can fall into more than one category, for example, e-mail and chat can represent both 1:1 and n:n communication. A topic of interest in this context is the double function CMC can have: It can be used for individual communication, but also for mass communication. This goes along with a double function that is very interesting in a learning setting, for example, in higher education. E-mail messages and discussion forum postings can simultaneously fulfill two successive functions: (1) interpersonal communication between two or more participants and subsequently (2) serve as an information pool for other participants. Chats that have a protocol option can also be used as an information pool for passive students. Fritsch (1998) coined the term *witness learning* to describe the indirect learning possibilities of learners who do not actively take part in interactions, but learn from witnessing the interactions of others. In virtual learning environments, participants have ranked “witnessing” (i.e., reading) the interactions of others high among the things they have learned from (Fritsch, 1998; Link, 2002).

As text-based CMC is not realized face-to-face but mediated via computers, the communication partners cannot directly experience nonverbal signals (e.g., facial expressions or gestures) or paraverbal signals (e.g., voice volume and tone). In practice, nonverbal and paraverbal signals are often compensated for by emoticons, inflectives, and other expressions created by entering characters on the keyboard.

Many studies, particularly those from a linguistic perspective, have investigated the style participants use in communicating. The most often noted phenomenon is no doubt the use of colloquial language in chat, e-mail, and even in discussion forums. This phenomenon is often accompanied by unconventional orthography, spelling and grammar errors, as well as slang expressions. Furthermore, the communication is influenced by a register embracing word creations taken from the language of computer hackers. If the model of Koch and Österreicher (1994) is applied to CMC, it becomes apparent that the linguistic characteristics of this type of written communication cannot simply be classified as totally oral or totally written: Here it is helpful to differentiate between the concept and medium of spoken and written language. Considering the communication style of CMC, it must be regarded as a hybrid language variety, displaying characteristics of both spoken and written language. As its usage norms are becoming conventionalised, some authors venture to propose that this communication style represents a new type of language which they refer to as netspeak or cybertalk, which cannot be compared to conventional communication (e.g., Crystal, 2001).

Studies with a focus on work-flow analysis often examine CMC as to its impact on the effectiveness of communication in professional contexts as well as on the dependency between communication style and the roles of the commu-
Computer-Mediated Communication in Virtual Learning Communities

mediation partners (e.g., communication between team colleagues vs. communication between employee and employer).

With regard to the literature and research reports published in the last 10 years, CMC plays an important role in nearly every community phenomenon. In social contexts, the style people use to communicate influences to a high degree the social relations and team dynamics.

**CMC THEORIES**

For the effective use of CMC in educational contexts, a variety of computer-mediated communication theories can provide insights into selecting appropriate CMC tools as well as understanding their limitations. Prevalent theories can be categorized into three large groups (Döring, 2003, p. 128):

1. Media choice (e.g., media richness theory: Daft & Lengel, 1984, 1986; Rice, 1992; social presence: Short, Williams, & Christie, 1976; Rice, 1993)
2. Media characteristics (e.g., cues-filtered-out model: Culnan & Markus, 1987; reduced social cues: Sproull & Kiesler, 1988)
3. Mediated communication behaviour (e.g., social information processing: Walther, 1992; Fulk, Schmitz, & Steinfeld, 1990).

Media choice theories focus on cognisant decision making about which medium to use for specific communicative tasks. The media richness theory (Daft & Lengel, 1984, 1986; Rice, 1992) is by far the most predominant theory of media choice. This theory defines a medium’s richness in terms of its capacity to carry information, feedback, channel, source, and language. Placing face-to-face communication at the richest end of the spectrum and numerical computer documents at the leanest, various communication media are then placed along this scale. In the media richness model of Reichwald, Möslin, Sachenbacher, & Englberger (2000, p. 57), which includes most forms of CMC, the spectrum from rich to lean media range from (1) face-to-face dialog, (2) video conference, (3) telephone/telephone conference, (4) voice mail, (5) computer conference, (6) telefax, (7) e-mail, (8) letter post and documentation. This theory contends that in organisations information is processed in order to reduce uncertainty or equivocality. Reducing uncertainty (e.g., communicating the postponement of a scheduled meeting) can be carried out best with lean media whereas reducing equivocality (e.g., a team meeting about a new project) requires a rich medium. Thus, the primary assertion of this theory is that the information richness of the task should correspond to the media richness of the medium.

To date, empirical studies have not been able to validate this theory.

Media characteristic theories examine the impact that media characteristics of CMC have on the communication process. The starting point is that CMC is typically text based. Accordingly, this results in reducing communication channels to text only, which in turn filters out physical and social cues. The cues-filtered-out approach (Culnan & Markus, 1987) propounds that since text-based CMC cannot communicate nonverbal or paraverbal information, very little social and sociodemographic information about the communication participants is transmitted. Additional research has found that the lack of social cues can be liberating, for example, in decreasing inhibition (Kiesler, Siegal, & McGuire, 1984).

Mediated communication behaviour theories focus on how participants behave during CMC, whether they exchange social information, form relational bonds, or use special Internet language. Social information processing (Walther, 1992) maintains that with time, CMC participants will develop communication skills to compensate for limitations of the medium. In contrast to the other
CMC theories, social information procession views the Internet as a new social environment in which over time communication partners find new ways in which to integrate nonverbal social information into their online behaviour.

**THE ROLE OF CMC IN VIRTUAL LEARNING COMMUNITIES IN HIGHER EDUCATION**

In view of the substantial use of CMC in many professional fields, especially in those dealing with research and development projects and distributed teamwork, higher education should prepare students to work effectively with CMC tools and familiarise them with the characteristics of CMC situations as well as with the impact these can have on work efficiency.

Even if many people know how to use an e-mail program or a chat tool or how to place a message in a Web-based bulletin board, this does not mean that they are automatically aware of the advantages and disadvantages of CMC. In this respect, there is still a significant lack of information and need for training which should be addressed in higher education. The boom in e-learning research projects has afforded most institutes of higher education the technical infrastructure necessary to offer students learning opportunities in virtual learning communities.

The following concept is just one example of how students can achieve the above-mentioned key competencies in virtual learning communities in higher education. The concept has been developed and successfully implemented in the project MEUM, a joint pilot project of the Flensburg University of Applied Sciences and the University of Hildesheim in Germany. Both institutes offer specialised degree programmes in translation and have teamed up to design and implement a distributed telelearning programme in which students can learn about and gain firsthand practical experience in Internet-based cooperative work in the field of translation. The students work in virtual teams on a concrete translation project. Here, we define a virtual team as a geographically distributed team, whose members communicate mainly via CMC. A detailed description of the MEUM project can be found in Wagner and Link (2003).

The blended learning courses offered in the context of MEUM are characterised by three phases:

1. Orientation phase in which the students receive initial information about the course didactics, objectives, and schedule and are organised into teams. This phase also includes an introduction to the Internet-based learning platform in which both learning modules and CMC tools (e-mail, chat, and discussion forums) are integrated;
2. Teamwork phase during which the virtual teams work autonomously to prepare and carry out their translation job; and
3. Team assessment and reflection phase in which the students reflect on their team and work process as well as on the impact the CMC and the overall virtuality had on their work.

In these courses, students are offered information on the theory and characteristics of CMC, for example, in Web-based learning modules. The virtual teams are free to choose which communication tools to use for the various tasks and phases of their virtual teamwork. This has resulted in all CMC tools being utilised. This combination of theory, task-based teamwork, and joint reflection phase has been rapidly accepted by the students and the reflection phase, in particular, is seen by them as a vital component of this concept.

For a successful transfer of this concept to other courses, it is important to consider the competencies required of students and instructors in a virtual learning community.
Computer-Mediated Communication in Virtual Learning Communities

Competencies of the instructors: Virtual learning communities require instructors to take on the supportive role of mentors or tutors in the background, functioning, for example, as consultants on demand. In general, they prepare the introduction of the virtual community and during the course monitor the activities of the communities from behind the scenes. In a preparatory phase, the instructor decides whether face-to-face meetings should be integrated, and if so, whether the team members should meet their team colleagues at the start. Prior to the course, students should be asked to give information about their media and professional skills as well as their prior experience with (virtual) teamwork. Instructors must also decide how teams should be formed: should students be given the task of building their own teams or is it advantageous to compose comparable teams according to student competency profiles?

As our own experience in virtual learning communities has shown, it is, on the one hand, very important to explain the role of the instructors in detail to the students and, on the other hand, for instructors to remain aware of their own role as tutors or mentors. By monitoring the work phase in the learning communities, instructors can decide when it might be necessary to intervene in the teamwork. This presupposes a didactic model in which the tutor/instructor has a consulting function in the background.

Competencies of the students: The following can be considered the requisite competencies for members in a virtual learning community as well as the fundamental skills and abilities that students should have at the end of the course.

The members of a virtual learning community are aware of the characteristics of and differences between the CMC tools chat, e-mail, and discussion forums. They have knowledge of the standard communication conventions for CMC (e.g., netiquette and chatiquette). The members are familiar with emoticons and other strategies for compensating for the lack of nonverbal and paraverbal signals in CMC, as well with moderation techniques, for example, in chats with more than two participants. The virtual community members know the importance of feedback for asynchronous communication, for example, a confirmation that an e-mail has arrived or a response to a note in a discussion forum to encourage the communication. They understand the role of small talk in CMC and the difficulties that go along with the mixture of task-oriented and relationship-oriented communication. It is important that community members recognise when communication results in misinterpretation and are able to identify the problems that CMC can produce in the learning community.

In the wake of globalisation, CMC and distributed virtual teams will become more and more commonplace in professional and educational contexts. At present we are still in an experimental phase that calls for more empirical studies into the efficient and effective use of these phenomena.

At the same time, future development of virtual learning communities should be extended across cultural and discipline boundaries. A new challenge in virtual learning communities will thus be intercultural and interdisciplinary cooperation.

CONCLUSION

In this article we presented a definition and classification of CMC. CMC is a phenomenon that is studied by a wide variety of disciplines: linguists, social psychologists, and computer scientists have proposed approaches to help understand the particularities and impacts of CMC. In addition to a discussion of selected CMC theories, we presented a sensibilization concept for CMC in higher education with the aim of helping students and instructors attain the key competencies required of members of a virtual (learning) community. The dissemination of distributed virtual
teamwork in professional fields requires new skill and competency requirements, which in turn must be addressed in educational training. Giving students the opportunity to learn how to utilise information and communication technology as well as to develop suitable strategies in CMC is a new challenge for higher education.

REFERENCES

**KEY TERMS**

**Blended Learning:** Learning design that combines various activities such as face-to-face meetings, Internet-based learning modules, and virtual learning communities.

**Chatiquette:** Standard rules of courtesy and correct behaviour for online chat.

**Computer-Mediated Communication (CMC):** Communication between humans using the computer as a medium.

**Emoticons:** A combination of punctuation marks and other special characters from the keyboard used to convey the tone of a computer-mediated communication message. For example, the combination :-) depicts smiling.

**Learning Platform:** Software systems that are used to deliver and support online teaching and learning. Learning platforms manage access to the platform and to learning materials and usually include various communication tools.

**Netiquette:** Standard rules of courtesy and correct behaviour on the Internet.

**Witness Learning:** A term coined by Dr. Helmut Fritsch, senior researcher at the FernUniversität in Hagen, Germany, that refers to the indirect learning possibilities of learners who do not actively take part in interactions, but learn from witnessing the interactions of others, for example, in online discussion forums.

This work was previously published in the Encyclopedia of Virtual Communities and Technologies, edited by S. Dasgupta, pp. 49-53, copyright 2006 by Information Science Reference; formerly known as Idea Group Reference (an imprint of IGI Global).
INTRODUCTION

Historically, computer security has its roots in the military domain with its hierarchical structures and clear and normative rules that are expected to be obeyed (Adams & Sasse, 1999). The technical expertise necessary to administer most security tools stems back to the time where security was the matter of trained system administrators and expert users. A considerable amount of money and expertise is invested by companies and institutions to set up and maintain powerful security infrastructures. However, in many cases, it is the user’s behavior that enables security breaches rather than shortcomings of the technology. This has led to the notion of the user as the weakest link in the chain (Schneier, 2000), implying that the user was to blame instead of technology. The engineer’s attitude toward the fallible human and the ignorance of the fact that technology’s primary goal was to serve human turned out to be hard to overcome (Sasse, Brostoff, & Weirich, 2001).

BACKGROUND

With the spreading of online work and networked collaboration, the economic damage caused by security-related problems has increased considerably (Sacha, Brostoff, & Sasse, 2000). Also, the increasing application of personal computers, personal networks, and mobile devices with their support of individual security configuration can be seen as one reason for the increasing problems with security (e.g., virus attacks from personal notebooks, leaks in the network due to personal wireless LANs, etc.) (Kent, 1997). During the past decade, the security research community has begun to acknowledge the importance of the human factor and has started to take research on
human-computer interaction into consideration. The attitude has changed from blaming the user as a source of error toward a more user-centered approach trying to persuade and convince the user that security is worth the effort (Ackerman, Cranor, & Reagle, 1999; Adams & Sasse, 1999; Markotten, 2002; Smetters & Grinter, 2002; Whitten & Tygar, 1999; Yee, 2002).

In the following section, current research results concerning the implications of user attitude and compliance toward security systems are introduced and discussed. In the subsequent three sections, security-related issues from the main application areas, such as authentication, email security, and system security, are discussed. Before the concluding remarks, an outlook on future challenges in the security of distributed context-aware computing environments is given.

USER ATTITUDE

The security of a system cannot be determined only by its technical aspects but also by the attitude of the users of such a system. Dourish et al. (2003) distinguish between theoretical security (e.g., what is technologically possible) and effective security (e.g., what is practically achievable). Theoretical security to their terms can be considered as the upper bound of effective security. In order to improve effective security, the everyday usage of security has to be improved. In two field studies, Weirich and Sasse (2001) and Dourish et al. (2003) explored users’ attitudes to security in working practice. The findings of both studies can be summarized under the following categories: perception of security, perception of threat, attitude toward security-related issues, and the social context of security.

Perception of security frequently is very inaccurate. Security mechanisms often are perceived as holistic tools that provide protection against threats, without any detailed knowledge about the actual scope. Therefore, specialized tools often are considered as insufficient, as they do not offer general protection. On the other hand, people might feel protected by a tool that does not address the relevant issue and thus remain unprotected (e.g., firewall protects against e-mail virus).

Perception of threats also reveals clear misconceptions. None of the users asked considered themselves as really endangered by attacks. As potential victims, other persons in their organization or other organizations were identified, such as leading personnel, people with important information, or high-profile institutions. Only a few of them realized the fact that they, even though not being the target, could be used as a stepping stone for an attack. The general attitude was that no one could do anything with the information on my computer or with my e-mails.

Potential attackers mainly were expected to be hackers or computer kids, with no explicit malevolent intentions but rather seeking fun. Notorious and disturbing but not really dangerous offenders, such as vandals, spammers, and marketers, were perceived as a frequent threat, while on the other hand, substantially dangerous attackers such as criminals were expected mainly in the context of online banking.

The attitude toward security technology was rather reserved. Generally, several studies reported three major types of attitudes toward security: privacy fundamentalists, privacy pragmatists, and privacy unconcerned (Ackerman et al., 1999). Users’ experiences played a considerable role in their attitude, as experienced users more often considered security as a hindrance and tried to circumvent it in a pragmatic fashion in order to reach their work objectives. Weirich and Sasse (2001) report that none of the users absolutely obeyed the prescribed rules, but all were convinced that they would do the best they could for security.

Additionally, users’ individual practices are often in disagreement with security technology.
People use legal statements in e-mail footers or cryptic e-mails, not giving explicit information but using contextual cues instead. In conjunction with such subsidiary methods and the fact that people often seem to switch to the telephone when talking about important things (Grinter & Palen, 2002) indicates the poor perception users have of security technology.

The feeling of futility was reported with respect to the need for constantly upgrading security mechanisms in a rather evolutionary struggle (i.e., if somebody really wants to break in, he or she will). As a result, personal accountability was not too high, as users believed that in a situation where someone misused his or her account, personal credibility would weigh more than computer-generated evidence, in spite of the fact that the fallibility of passwords is generally agreed.

The social context has been reported to play an important role in day-by-day security, as users are not permanently vigilant and aware of possible threats but rather considered with getting their work done. Therefore, it is no wonder that users try to delegate responsibility to technical systems (encryption, firewalls, etc.), colleagues and friends (the friend as expert), an organization (they know what they do), or institutions (the bank cares for secure transfers). Most people have a strong belief in the security of their company’s infrastructure. Delegation brings security out of the focus of the user and results in security unawareness, as security is not a part of the working procedure anymore.

Whenever no clear guidelines are available, people often base their practice on the judgments of others, making the system vulnerable to social engineering methods (Mitnick, Simon, & Wozniak, 2002). In some cases, collaboration appears to make it necessary or socially opportune to disclose one’s password to others for practical reasons, technical reasons, or as a consequence of social behavior, since sharing a secret can be interpreted as a sign of trust. Such sharing is a significant problem, as it is used in social engineering in order to obtain passwords and to gain access to systems.

Dourish et al. (2003) came to the conclusion that “where security research has typically focused on theoretical and technical capabilities and opportunities, for end users carrying out their work on computer systems, the problems are more prosaic” (p. 12). The authors make the following recommendations for the improvement of security mechanisms in the system and in the organizational context:

- Users should be able to access security settings easily and as an integral part of the actions, not in the separated fashion as it is today; therefore, security issues should be integrated in the development of applications (Brostoff & Sasse, 2001; Gerd tom Markotten, 2002).
- It is necessary that people can monitor and understand the potential consequences of their actions (Irvine & Levin, 2000) and that they understand the security mechanisms employed by the organization.
- Security should be embedded into working practice and organizational arrangement, and visible and accessible in everyday physical and social environment (Ackerman & Cranor, 1999).
- Security should be part of the positive values in an organization. So-called social marketing could be used to establish a security culture in a company.
- The personal responsibility and the danger of personal embarrassment could increase the feeling of personal liability.
- The importance of security-aware acting should be made clear by emphasizing the relevance to the organization’s reputation and financial dangers.
As has been shown, the design and implementation of security mechanisms are closely interlinked to the psychological and sociological aspects of the user’s attitude and compliance toward the system. Any security system is in danger of becoming inefficient or even obsolete if it fails to provide adequate support and motivate users for its proper usage. The following sections discuss these findings in the context of the main application domains of computer security.

AUTHENTICATION

Information technology extends our ability to communicate, to store and retrieve information, and to process information. With this technology comes the need to control access to its applications for reasons of privacy and confidentiality, national security, or auditing and billing, to name a few. Access control in an IT system typically involves the identification of a subject, his or her subsequent authentication, and, upon success, his or her authorization to the IT system.

The crucial authentication step generally is carried out based on something the subject knows, has, or is. By far the most widespread means of authentication is based on what a subject has (e.g., a key). Keys unlock doors and provide access to cars, apartments, and contents of a chest in the attic. Keys are genuinely usable—four-year-olds can handle them. In the world of IT, something the subject knows (e.g., a password or a secret personal identification number [PIN]) is the prominent mechanism.

The exclusiveness of access to an IT system protected by a password rests on the security of the password against guessing, leaving aside other technical means by which it may or may not be broken. From an information theoretic standpoint, a uniformly and randomly chosen sequence of letters and other symbols principally provides the greatest security. However, such a random sequence of unrelated symbols also is hard to remember, a relation that is rooted in the limitation of humans’ cognitive capabilities.

As a remedy, a variety of strategies were invented to construct passwords that humans can memorize more easily without substantially sacrificing the security of a password (e.g., passwords based on mnemonic phrases). For instance, Yan, et al. (2000) conducted a study with 400 students on the effect of three forms of advice on choosing passwords. They found, for example, that passwords based on pass phrases were remembered as easily as naively chosen passwords, while being as hard to crack as randomly chosen passwords. Insight into human cognition also has led to the investigation of alternatives such as cognitive passwords (Zviran & Haga, 1990), word associations (Smith, 1987), pass phrases (Spector & Ginzberg, 1994), images (Dhamija & Perrig, 2000), or pass faces (Brostoff & Sasse, 2000).

Authentication in public places, as is the case with automatic teller machines (ATM), has turned out to be vulnerable to attacks, where criminals obtain a user’s PIN by using cameras or other methods of observation in so-called shoulder-surfing attacks (Colville, 2003). In order to obscure the numbers entered by the user and thus hamper the recording of the necessary PIN, several techniques have been proposed (Hopper & Blum, 2001; Wilfong, 1997). Recently, Roth, et al. (2004) suggested variants of cognitive trapdoor games to protect users against shoulder-surfing attacks. In this approach, the buttons on a PIN pad are colored either black or white, and the user has to decide whether the number to be entered is in the black or white group. As the colors are changing randomly, the user has to enter the same number three to four times to complete an input. By blurring the response set with so-called shadows, this method can be made resistant against camera attacks. Even though this approach is slightly more complicated than the classical approach, this technique has proven to be accepted by the user in an experimental setting.
E-MAIL SECURITY

Before the middle of the 1970s, cryptography was built entirely on symmetric ciphers. This meant that in order for enciphered communication to take place, a secret key needed to be exchanged beforehand over a secure out-of-band channel. One way of doing that was to send a trusted courier to the party with whom one intended to communicate securely. This procedure addressed two important issues: the secret key exchange and the implicit authentication of the exchanged keys. Once established, the keys could be used to secure communication against passive and active attacks until the key was expected to become or became compromised.

When asymmetric cryptography (Diffie & Hellman, 1976; Rivest, Shamir, & Adleman, 1978) was invented in the 1970s, it tremendously simplified that task of key exchange, and gave birth to the concept of digital signatures. Asymmetric cryptography did not solve the problem of authenticating keys per se. Although we now can exchange keys securely in the clear, how could one be certain that a key actually belonged to the alleged sender? Toward a solution to this problem, Loren Kohnfelder (1978) invented the public key certificate, which is a public key and an identity, signed together in a clever way with the private key of a key introducer whom the communicating parties need to trust. This idea gave rise to the notion of a public key infrastructure (PKI). Some existing models of public key infrastructures are the OpenPGP Web of Trust model (RFC 2440) and the increasingly complex ITU Recommendation X.509-based PKIX model (RFC 3280) (Davis, 1996; Ellison, 1996, 1997; Ellison & Schneier, 2000).

In applications such as electronic mail, building trust in certificates, exchanging keys, and managing keys account for the majority of the interactions and decisions that interfere with the goal-oriented tasks of a user and that the user has difficulty understanding (Davis, 1996; Gutmann, 2003; Whitten & Tygar, 1999). At the same time, the majority of users only has limited understanding of the underlying trust models and concepts (Davis, 1996) and a weak perception of threats (see previous discussion). Consequently, they avoid or improperly operate the security software (Whitten & Tygar, 1999).

In the safe staging approach, security functions may be grouped into stages of increasing complexity. A user may begin at a low stage and progress to a higher stage once the user understands and masters the security functions at the lower stages. The safe-staging approach was proposed by Whitten & Tygar (2003), who also pioneered research on the usability of mail security by analyzing users’ performances when operating PGP (Whitten & Tygar, 1999).

SYSTEM SECURITY

Computer systems progressed from single user systems and multi-user batch processing systems to multi-user time-sharing systems, which brought the requirement to sharing the system resources and at the same time to tightly control the resource allocation as well as the information flow within the system. The principal approach to solving this is to establish a verified supervisor software also called the reference monitor (Anderson, 1972), which controls all security-relevant aspects in the system.

However, the Internet tremendously accelerated the production and distribution of software, some of which may be of dubious origin. Additionally, the increasing amounts of so-called malware that thrives on security flaws and programming errors lead to a situation where the granularity of access control in multi-user resource-sharing systems is no longer sufficient to cope with the imminent threats. Rather than separating user domains, applications themselves increasingly must be separated, even if they run on behalf of the same user. A flaw in a Web browser should
not lead to a potential compromise of other applications and application data such as the user’s e-mail client or word processor. Despite efforts to provide solutions to such problems (Goldberg et al., 1996) as well as the availability of off-the-shelf environments in different flavors of Unix, fine-grained application separation has not yet been included as a standard feature of a COTS operating system.

Even if such separation were available, malicious software may delude the user into believing, for example, that a graphical user interface (GUI) component of the malware belongs to a different trusted application. One means of achieving this is to mimic the visual appearance and responses of the genuine application. One typical example would be a fake login screen or window. Assurance that a certain GUI component actually belongs to a particular application or the operating system component requires a trusted path between the user and the system. For instance, a secure attention key that cannot be intercepted by the malware may switch to a secure login window. While this functionally is available in some COTS operating systems, current GUIs still provide ample opportunity for disguise, a problem that also is eminent on the Web (Felten, Balfanz, Dean, & Wallach, 1997). One approach to solving this problem for GUIs is to appropriately mark windows so that they can be associated with their parent application (Yee, 2002). One instance of a research prototype windowing system designed with such threats in mind is the EROS Trusted Window System (Shapiro, Vanderburgh, Northup, & Chizmadia, 2003).

FUTURE TRENDS

Mobile computing and the emergence of context-aware services progressively are integrating into new and powerful services that hold the promise of making life easier and safer. Contextual data will help the user to configure and select the services the user needs and even might elicit support proactively. Far beyond that, Ambient Intelligence (IST Advisory Group, 2003) is an emerging vision of dynamically communicating and cooperating appliances and devices in order to provide an intelligent surrounding for tomorrow’s citizens. Radio frequency identification transmitters (RFID) already have been discussed with respect to their implications on privacy (Weis, 2004). Certainly, one person’s contextual awareness is another person’s lack of privacy (Hudson & Smith, 1996). In the future, the development of powerful and usable security concepts for applying personal information to the context and vice versa is one of the greatest challenges for today’s security engineers and human-computer interaction research (Ackerman, Darell, & Weitzner, 2001). To accomplish this task seems crucial for future acceptance and for chances of such technologies without them becoming a “privacy Chernobyl” (Agre, 1999).

CONCLUSION

The view of the user as the weakest link and potential security danger finally has turned out to be an obsolescent model. Security engineers and perhaps, more importantly, those people who are responsible for IT security have noticed that working against the user will not do, and instead, they have decided to work with and for the user. During the past years, an increasing number of research has focused on the issue of making security usable, addressing the traditional fields of authentication, communication, and e-mail and system security. This article has given a brief overview of some of the work done so far. In order to make information technology more secure, the user is the central instance. The user must be able to properly use the security mechanisms provided. Therefore, understanding users’ needs
Human-Computer Interaction and Security

and identifying the reasons that technology fails to convince users to employ it is crucial. The first part of this article summarized some work done by Dourish, Weirich, and Sasse that provided important insights. But much work still has to be done.

Future technology will build even more on the integration and sharing of heterogeneous sources of information and services. The tendency toward distributed and location-based information infrastructures will lead to new security problems. Feeling safe is an important aspect of acceptance. The success of tomorrow’s systems also will depend on the user’s feeling safe while sharing information and using services, which has already been shown during the first stage of e-commerce. Therefore, making security usable is an important aspect of making security safe.

Human-Computer Interaction and Security

KEY TERMS

Asymmetric Cryptography: A data encryption system that uses two separate but related encryption keys. The private key is known only to its owner, while the public key is made available in a key repository or as part of a digital certificate. Asymmetric cryptography is the basis of digital signature systems.

Public Key Infrastructure (PKI): The public infrastructure that administers, distributes, and certifies electronic keys and certificates that are used to authenticate identity and encrypt information. Generally speaking, PKI is a system of digital certificates, certification authorities, and registration authorities that authenticate and verify the validity of the parties involved in electronic transactions.

Shoulder Surfing: The practice of observing persons while entering secret authentication information in order to obtain illegal access to money or services. This often occurs in the context of PIN numbers and banking transactions, where shoulder surfing occurs together with the stealthy duplication of credit or banking cards.

Social Engineering: The technique of exploiting the weakness of users rather than software by convincing users to disclose secrets or passwords by pretending to be authorized staff, network administrator, or the like.

Spoofing: The technique of obtaining or mimicking a fake identity in the network. This can be used for pretending to be a trustworthy Web site and for motivating users (e.g., entering banking information), pretending to be an authorized instance that requests the user’s password, or making users accept information that is believed to come from a trusted instance.

Types of Authentication: Authentication generally can be based on three types of informa-
tion: by some thing the user has (e.g., bank card, key, etc.), by something the user knows (e.g., password, number, etc.), or by something the user is (e.g., biometric methods like fingerprints, face recognition, etc.).

Chapter 1.26
Security for Ubiquitous Computing

Tobias Straub
Fraunhofer Institute for Secure Information Technology, Germany

Andreas Heinemann
Technical University of Darmstadt, Germany

ABSTRACT

Taking typical ubiquitous computing settings as a starting point, this chapter motivates the need for security. The reader will learn what makes security challenging and what the risks predominant in ubiquitous computing are. The major part of this chapter is dedicated to the description of sample solutions in order to illustrate the wealth of protection mechanisms. A background in IT security is not required as this chapter is self-contained. A brief introduction to the subject is given as well as an overview of cryptographic tools.

INTRODUCTION

Mark Weiser’s vision of ubiquitous computing (UC) raises many new security issues. Consider a situation where a large number of UC peers interact in a spontaneous and autonomous manner, without previously known communication partners and without a common security infrastructure. Such extreme conditions make it difficult to apply established security methods that have been tailored for “classical” information technology (IT). Virgil Gligor emphasizes this by comparing the Internet cliche where “processing is free and physically protected, but communication is not” with the new cliche about UC where “neither processing nor communication is free and physically protected” (Gligor, 2005).

This chapter gives a systematic introduction into the field of security for UC. It is structured as follows: first (the section “Four UC Settings”), we illustrate the diversity of UC systems and applications in order to raise the reader’s awareness of security questions. Our discussion focuses on four representative UC settings. For each of them, a characteristic application scenario is given. The diversity of the settings, for example, concerning presumed knowledge about components or
system complexity, has direct implications for which mechanisms are appropriate to achieve a desired IT security objective.

The section “A Taxonomy of UC Security” starts with an introduction to basic terminology explaining the objectives of IT security as well as the threat model. UC security can be regarded from two different viewpoints: The special characteristics of UC may lead to known and new security risks, if not addressed appropriately. In addition, limitations concerning resources and infrastructure pose a number of challenges in order to achieve desired security objectives.

A compact overview of cryptographic tools suitable to enforce those objectives is given in the section “Overview of Cryptographic Tools”. A brief explanation of cryptographic primitives like ciphers, hash functions, and signatures is provided for the nonspecialist reader. A discussion of the potential and limitations of cryptography in UC concludes the section.

After having learned the particularities and challenges of UC systems with respect to security, we look at sample solutions to mitigate these limitations. A selection of elaborated approaches for secure UC systems is given in the section “Sample Solutions”. They tackle the issues of privacy and availability as well as the establishment of secure communication.

A brief summary and a list of references for further reading conclude this chapter.

FOUR UC SETTINGS

In order to pave the way for the development of a systematic view on UC characteristics and limitations in the section “A Taxonomy of UC Security”, we sketch four representative settings. Each setting exhibits one or more security-related properties. They are termed mobile computing, ad hoc interaction, smart spaces, and real-time enterprises.

Mobile Computing

Mobile computing supports mobile users with connectivity and access to services and backend systems while being on the move. A synonymous term is nomadic computing, emphasizing the goal of providing a working environment more or less equivalent to that of a desktop user. The widespread availability of cellular networks and 802.11 WiFi allows a field worker to connect to an arbitrary service on the Internet or to the company’s backend at almost any place and at any time.

Mobile computing relies on a given infrastructure managed by a provider, for example, a cellular network company. This fact has implications for security: In order to access a service, a user needs to register with a provider. Thus, the user group is closed and the provider controls access to the infrastructure. In addition, users are not able to act in an anonymous manner.

Mobile devices can easily get lost, for example left behind in the proverbial taxi (see http://www.laptopical.com/laptops-lost-in-taxi.html). In case of theft, an attacker might be able to impersonate the legitimate device owner or learn her private data like business contacts or personal email. This physical threat is given whenever mobile devices are considered.

Scenario 1: The Mobile Salesman

While on the road, a salesman needs to regularly download up-to-date client reports from his company’s databases. His laptop is equipped with several wireless communication interfaces which can be used to connect via different service providers depending on what kind of service/infrastructure is available.

At the client’s office, there is a WiFi network the salesman can access. There are also some networked printers available for guests. However, it is unclear to what extent the infrastructure can be trusted.
This scenario raises three major issues: Firstly, the protection of communication (from the salesman's device to the company backend) over potentially insecure channels. Secondly, the secure storage of company internals on his laptop. Secure tunneling, VPNs (virtual private networks), and hard disk encryption are standard technologies in this field. The necessary cryptographic tools are explained in the section “Overview of Cryptographic Tools”. However, the aspect of secure device association, discussed, for example, by Balfanz, Smetters, Stewart, and Wong (2002), is something new. Later in this chapter, we answer the following questions: Is there a way to securely send a confidential document over the air to a printer located in the office? Does it help if the salesman selects a printer close to him equipped with a secondary communication interface?

**Ad Hoc Interaction**

In contrast to mobile computing, the second setting does not rely on an infrastructure provider. Instead of that, UC devices build the infrastructure on their own by establishing temporary, wireless, and ad hoc communication links between them. On the application layer, they expose a spontaneous interaction behavior. A typical characteristic is the lack of a central instance allowing or restricting participation. A priori, there are no given or managed user groups; all devices are free to join. Plus, users and devices might act anonymously.

Here we illustrate a collaboration scenario based on spontaneous interaction. This type of communication is typical for *Opportunistic Networks* which are discussed in depth in the chapter “Opportunistic Networks”.

**Scenario 2: Passive Collaboration in Opportunistic Networks**

*In an Opportunistic Network, passers-by exchange information, for example digital advertisements (Straub & Heinemann, 2004), while being colocated. After an initial configuration, devices interact autonomously and without users’ attention. Information dissemination is controlled by profiles stored on the users’ devices. Such a profile expresses a user’s interest in and knowledge about some pieces of information to share.*

The particularities of ad hoc interaction pose numerous security challenges. On the one hand, devices do not already know each other when they start to communicate. On the other hand, personal data is kept on the devices and exchanged with strangers. As a consequence, privacy is inherently at risk if systems are not designed carefully.

**Smart Spaces**

Smart spaces, which form our third UC setting, emphasize user-friendliness and user empowerment as well as support for human interactions. Interaction within a smart space happens in an unobtrusive way. The use of contextual information (see chapter “Context Models and Context Awareness”) plays also an important role here. Sometimes, it is assumed that users carry some type of digital identification and/or other devices with or on them.

Due to the sensing and tracking capabilities of a smart space, user privacy is at stake. Location privacy is an important field of UC research; an overview is given by Görlach, Heinemann, Terpstra, and Mühlhäuser (2005). In addition, due to the volatile nature of smart spaces, concepts like trust (see Chapter 15) and reputation play an important part in these kinds of applications. We take patient monitoring in a hospital as an example to illustrate a smart space.

**Scenario 3: Patient Monitoring**

*In a hospital, all records of patients are digitally stored and maintained in a central database. Records are updated with the results of physical*
examinations or continuous monitoring. Husemann and Nidd (2005) describe a middleware capable of integrating a wide range of medical analyzers that have a common wireless interface. Consider a battery driven heartbeat monitor which is attached to the body and sends measurements to the database. The data can be used as well for a patient surveillance system that triggers an alarm in case of an anomaly.

This scenario raises a number of security issues: for new patients the heartbeat monitor has to be unambiguously and securely associated with their record. The data from the monitor needs to go to the right record, communication needs to be protected, and the correctness of the data must be assured. In addition, after a patient leaves the hospital, the heartbeat monitor needs to be detached from the digital record for reuse. The resurrecting duckling (Stajano & Anderson, 1999) security policy framework helps in this setting. It is described in the section “Sample Solutions”.

Real-Time Enterprises

Real-time enterprises, which are defined in the preface of this book, are an effort to leverage UC technology and methods within enterprises. A driving force behind these efforts is the goal of having immediate access to comprehensive and up-to-date information about processes and procedures within an enterprise. This allows management to react very flexibly to variances in the market and to increase customer support and satisfaction. For example, an enterprise with detailed real-time information on all production steps, including delivery statuses of subcontractors, can provide a customer with very accurate information on when an order will be delivered.

Scenario 4: RFID-Based Warehouse Management

Radio frequency identification (RFID) offers a variety of opportunities in tracking goods (see e.g., Fleisch & Mattern, 2005). Suppose all goods stocked at a warehouse are tagged with an RFID transponder. With the corresponding readers integrated into storage racks, the process of stocktaking can be completely automated and inventory information is available in real-time.

The use of RFID allows for more efficient stocking, product locating, and product theft protection, to name a few. The deployment of tags and readers within a company gives rise to security questions, for instance, those of industrial espionage. A competitor, equipped with a mobile RFID reader, might be able to derive useful information about a company by reading their product tags. RFID tags should also be looked at from a privacy point of view as they—under certain conditions—may allow the surveillance and tracking of humans.

RFID privacy is currently also a hot topic in the context of machine-readable travel documents. Privacy is discussed with respect to biometric data like photos and fingerprints stored on the chip. Another question is whether ID cards can be used to create movement profiles of their holder. The reader is referred to Knospe and Pohl (2004) for an overview of RFID security. We come back to this issue in the section “Sample Solutions”.

A TAXONOMY OF UC SECURITY

The beginning of this section provides a compact introduction to IT security by explaining the common objectives and the threats to them. We then formulate two views on UC security issues. In section “First View: UC Characteristics and
Associated Risks,” we explain which and how typical characteristics of UC lead to well-known, but also new risks that demand appropriate countermeasures. UC limitations concerning resources and deployed infrastructures are in focus of the second view in the section “Second View: UC Limitations and Associated Challenges”. These limitations give rise to security challenges that require novel methods, some of which are presented in the section “Sample Solutions”.

Basic Terminology and Objectives of IT Security

Security of IT systems is usually discussed in the following way: First, assets (and their respective value) are identified. The notion of assets covers data as well as hardware. With respect to our four scenarios, data that has to be protected, for instance, comprises:

- Confidential documents (Scenario 1),
- An individual’s habits and preferences (Scenario 2),
- Medical information (Scenario 3),
- The stock list at a warehouse (Scenario 4).

When speaking of the protection of data, we mean that particular attributes are preserved. In the information security community the mnemonics CIA or CIAA are often used to refer to the following fundamental protection objectives:

- **Confidentiality (C):** Refers to the aim of keeping pieces of information secret from unauthorized access.
- **Integrity (I):** Is the requirement that data is safe from changes, be it either accidentally or deliberately.
- **Authenticity (A):** Concerns itself with the genuineness of messages or the identity of entities in a networked system.

These objectives can be achieved by cryptography as we will see below. In this respect, the next objective is different as it typically requires noncryptographic efforts as well.

- **Availability (A):** Means the provisioning of a system’s services to its users in a reliable way.

An attacker may try to prevent legitimate use in a so-called denial-of-service (DoS) attack. Demanding a large portion of (computational and/or network) resources is a strategy to slow down the system. Another flavor of DoS is the blocking of communication links between legitimate parties. Designing a UC system for redundancy and diversity is a standard way towards achieving availability (see e.g., Vogt, 2005). This can be done, for instance, by using peer-to-peer networks, the replication of information, or distributed computing facilities. Intrusion-detection systems, which are a common protection technology for computer systems in an organization, are starting to attract attention in the UC community (Robinson, 2005). Bahl, Chandra, Padhye, Ravindranath, Singh, Wolman (2006) describe a system to fight DoS attacks on corporate wireless networks and to detect malicious mobile devices.

Threat Modeling

Having discussed basic terminology and objectives, we now turn to a common abstract network model to describe security threats: Two parties exchange messages over a channel to which an attacker has access, too. This notion captures any kind of attackers (computer systems, individuals, organizations) and is independent of the data transport medium itself. There is no need to differentiate between the transmission and the storage of data as the latter can be seen as a special case of the model.
We follow the security community's convention in using the names Alice and Bob for the legitimate actors (instead of simply numbering them serially) and in calling the attacker Mallory (“malicious”). Mallory may change data Alice sends to Bob, may generate her own messages under the name of another person, or simply eavesdrop on their connection. An attack of the latter kind is called passive while the other two are called active. A passive attacker can compromise confidentiality at best, but an active one—who is also called man-in-the-middle (MITM)—targets at all CIAA goals. Acting as a MITM, Mallory sits in between the communication link, making Alice believe she is Bob and spoofs Bob into believing she is Alice.

Attacks are typically directed toward more than one of the before-mentioned security objectives. For instance, Mallory may launch a DoS attack in order to paralyze the system’s defense mechanisms.

The risk that a system may become compromised is proportional to both its vulnerabilities and the threats acting upon it. Risks have to be identified and rated in the light of the corresponding assets’ value. Threat perception can be very subjective: While one individual cares about data emitted by her UC device, which might be linked back to her, another does not. Furthermore, not all objectives are equally important in practice. For instance, a bank primarily has a vital interest in keeping its account data’s integrity, but a research lab emphasizes confidentiality. The choice of algorithms and security also takes into consideration the (assumed) attacker’s strategy and resources, especially computational power.

First View: UC Characteristics and Associated Risks

In order to put the UC vision to work, most scenarios, including the ones described in the last section, rely on wireless communication between nodes. Communication might happen in an ad hoc manner as illustrated in the ad hoc interaction setting; other applications might ask for a wireless multi-hop communication (see sensor networks in the chapter “Wireless and Mobile Communication”). Wireless communication makes eavesdropping very easy as radio signal are usually emitted in all directions. They can be received by anyone in the senders’ vicinity without her noticing it. MITM attacks are feasible in the case of multi-hop wireless communication and they do not even require the attacker to be physically close to the victim. In addition, wireless ad hoc communication bears the risk of impersonation, that is, an attacker might be able to steal a peer’s credential by eavesdropping and use it to access a certain service.

The pervasive nature of UC introduces even more risks. Sensor nodes or RFID tags for example, are physically exposed, unmanaged, and unsupervised. This bears the risks of device and/or data theft as well as device manipulation. As a consequence, access to the data stored on the device must be carefully protected in order to prevent identity theft (Eckert, 2005). The Blackberry PDA for instance is a centrally manageable system that supports a remote “kill” command to erase data on a stolen device (Greiner, 2006).

UC devices are often battery-powered, which allows for a DoS attack called sleep deprivation torture (Stajano & Anderson, 1999): By constantly sending requests to a device, an attacker can quickly drain its battery, thus rendering the device useless. Last but not least, the UC settings offer the capability of tracing objects or humans. This feature is useful in many UC applications like the real-time enterprise setting, but may violate user’s privacy. Networked sensors, for instance, may gather a good deal of personal information that can be used to build user profiles.

The characteristics in UC and their corresponding risks are summarized in Table 1. In the section “Overview of Cryptographic Tools” we cover appropriate countermeasures.
Second View: UC Limitations and Associated Challenges

Our second view on UC security concerns resource and infrastructure limitations of UC and their corresponding challenges. The functionality provided by UC devices varies widely and is limited by a number of parameters. These include device capabilities—concerning, for example, memory capacity, energy supply, CPU power, and the user interface—or connectivity which is characterized among others by network coverage, bandwidth, environmental conditions (like shielding or speed in case of moving devices).

Since a UC device can be less powerful than a desktop computer, it is important to use appropriate, that is, lightweight, security mechanisms. Otherwise, wasting memory and energy resources would achieve the exact opposite effect of keeping the system safe. Observe that a slow CPU might take significant time to carry out sophisticated cryptographic operations which may negatively affect the user experience. User interface capabilities may also limit the choice of appropriate methods, too: For example, a mobile device with a voice only user interface such as described by Ait-enbichler, Kangasharju, and Mühlhäuser (2004), demands different authentication methods to a device that comes with a keyboard. At the bottom end, very small and feeblish UC devices like passive RFID chips are found. These devices do not even come with a user interface at all. A limited user interface makes it difficult to establish what is called a trusted path. This is a mechanism to ensure that users can assert that they are interacting with a genuine system or program instead of one controlled by an attacker (for instance when asked for a password).

The absence of a centralized authority is typical for UC systems like the ad hoc interaction setting presented in section “Ad Hoc Interaction”. This makes it hard to build an infrastructure where UC peers can authenticate each other in order to communicate securely. Another consequence is the lack of common support for trust and policy decision. The following chapter discusses appropriate countermeasures for this issue. Alternative methods for entity authentication based on out-of-band communication schemes are the subject of section “Out-of-Band Channels”.

The limitations corresponding to UC security and their induced challenges are summarized in Table 2. Selected methods that address these challenges are discussed in section “Sample Solutions”.

OVERVIEW OF CRYPTOGRAPHIC TOOLS

This section provides a compact overview of cryptographic tools which are suitable to enforce the security objectives introduced in the section “A Taxonomy of UC Security”. It serves as a basis for the following discussion of the solutions addressing UC characteristics and challenges. Cryptographic primitives, namely symmetric and public key cryptosystems, hash functions, and authentication schemes, are the building blocks of more complex techniques and protocols. We also introduce some general rules of cryptography and reason about security parameters. At the end of this section we turn to the potentials and limitations of cryptography in a UC setting. Readers with previous knowledge in the area of cryptography may directly proceed to section “Potential and Limitations of Cryptography in UC.”

Symmetric Cryptosystems

Messages can be encrypted to prevent disclosure of their content and ensure confidentiality. Encryption is a transformation that renders plaintext, that is, the original message in its readable form, into ciphertext which is unintelligible to an outsider. The reverse transformation is called decryption. In order to give Alice and Bob a competitive edge, there must be some information Mallory does not have. The encryption and decryption function of all modern cryptosystems (or ciphers) are parameterized by keys. A key is a short fixed-length piece of data (while the plaintext may be of arbitrary length). It has to be kept secret from Mallory as only the correct key allows successful decryption of the ciphertext.

As early as the 19th century, cryptographer Kerckhoff claimed the following important law: A cryptosystem’s strength should not be based on the assumption that its algorithm is kept secret, but only on the attacker’s uncertainty regarding the key. An elementary security requirement is the fact that it should be unfeasible for Mallory to simply try out all possible keys by a brute-force attack. This imposes a lower bound on the cardinality of the set of all possible keys and demands that keys be generated randomly.

The distinction whether the same key is used for encryption and decryption or not may seem marginal at first sight, but is in fact crucial. Symmetric cryptosystems require two or more communication partners to know the same shared key. Modern symmetric cryptosystems use keys of bitlength 112, 168 (3DES) or 128, 192, 256 (AES). As a rule of thumb, keys shorter than 80 bits should be used with great care. A good place to look up reliable key lengths based on cryptographic analysis is the Website http://www.keylength.com.
On this occasion, we exhibit a problem common to all symmetric ciphers: The use of shared keys implies a secure key distribution step before the actual communication takes place. Key distribution is often a problem as it needs out-of-band mechanisms, that is, an additional communication channel not accessible to the attacker. We will come back to this issue in the context of UC in the section “Out-of-Band Channels”. Another downside of shared keys is that the risk grows proportional to the number of group members. If one device falls into Mallory’s hands, she will be able to read all messages of the group. A real-world example for the use of shared keys is 802.11 WEP (“Wired Equivalent Privacy”, see, for example, Eckert, 2006).

**Asymmetric Cryptosystems and PKI**

The key distribution problem can be avoided by using asymmetric cryptosystems, which are synonymously called public key cryptosystems. In this case, encryption and decryption use different keys, such that these functions can be effectively separated. The respective keys are denoted public key and private key. Such a key pair has to satisfy certain mathematical conditions depending on the particular cryptosystem. Bob solely has to keep his private key secret, but can make the corresponding public key available to Alice or everybody else in the world—including Mallory—as it is infeasible to compute the private key from the public key. Public key encryption is thus an example of a so-called one-way function since the ciphertext can be computed efficiently, while inversion is infeasible. More specifically, public key encryption falls into the category of one-way functions with trapdoor as knowledge of the private key allows the inversion of the mapping. We will see below that asymmetry is an important pillar of modern cryptography.

The RSA cryptosystem, named after R. Rivest, A. Shamir, and L. Adleman (1978), is the most prominent example of an asymmetric cryptosystem. Typical key lengths are 1024, 2048, or 4096 bit. Its security is based on the presumed intractability of the factorization of large composite numbers. The ElGamal cryptosystem in contrast is based on the problem of computing discrete logarithms in finite cyclic groups (a typical group size is $2^{160}$ or $2^{230}$). A standard construction for ElGamal is to use a subgroup of the multiplicative group of $\mathbb{Z}/p\mathbb{Z}$, where $p$ is a prime (typically 1024 or 2048 bits in length). Elliptic curves (EC) over finite fields can also serve as a mathematical structure for ElGamal encryption (see, e.g., Hankerson, Menezes, and Vanstone, 2004) for an introduction to EC cryptography.

Observe that public key cryptography alleviates the problem of confidential secret key distribution for the price of authentic public key distribution in the following way: Alice who wants to send a private message to Bob needs to have his genuine public key $K_B$. If Mallory manages to foist her key $K_M$ on Alice, the message would be encrypted for her and not for Bob. Digital certificates are a common solution to this problem. A certificate is a statement linking a public key to an identity (e.g., a user’s name, a device address, or a pseudonym). In order to prevent certificates from being forged they are digitally signed (see the following section for an explanation of digital signatures). Certificates form the basis of a so-called public key infrastructure (PKI), an environment where the authenticity of public keys is assured.

**Hash Functions**

In order to ensure data integrity, some kind of redundancy has to be added to the payload. A modification detection code (MDC) is a hash algorithm, that is, a function that compresses bitstrings of arbitrary finite length to bitstrings of fixed length. State-of-the-art algorithms like RIPEMD-160 (Dobbertin, Bosselaers, & Preneel, 1996) or SHA-1 (Eastlake & Jones, 2001) produce outputs with a length of 160 bit, which should be
considered the lower bound due to security reasons. To be useful for integrity protection, a hash function has to be 2nd preimage resistant: Given an input \( x \) that hashes to \( h(x) \), an attacker must not be able to find a value \( y \neq x \) such that \( h(y) = h(x) \). Such a pair of different inputs that result in the same hash value is called a collision. Collisions always exist due to the pigeon-hole principle since the co-domain is finite while the domain is infinite. Cryptographic hash functions must be collision-resistant, that is, finding concrete collisions must be computationally infeasible. This allows us to protect data of arbitrary length against modifications by storing \( h(x) \), a small piece of information, in a safe place. A widespread application of this mechanism is integrity-protected software distribution via download mirror sites on the Internet. Flipping a single bit in \( x \) results in a hash value that differs in about half of the bits from \( h(x) \) if \( h \) is one of the common hash functions.

Message authentication codes (MACs) are hash functions that are additionally parameterized with a secret key. Assume that Alice and Bob share a key \( k \), which for instance has been established in a key exchange scheme as explained below. Alice adds a MAC \( h_k(x) \) to her message \( x \) to Bob. From the pair \( (x, h_k(x)) \) Bob can tell that the message came from her since it is infeasible for Mallory to create a pair \( (y, h_k(y)) \) without knowing \( k \). Remember that a MDC does not have this property, since Mallory may change \( x \) to \( y \) and compute the (unkeyed) hash function \( h(y) \). MACs in turn not only provide data origin authentication, but also integrity as Bob could detect a modification \( x' \neq x \) because the received \( h_k(x) \) would not match the value \( h_k(x') \) he computed himself. Each MDC \( h \) can be extended to a MAC in the following way: On input \( x \), compute \( h(k \parallel p_1 \parallel h(k \parallel p_2 \parallel x)) \) where \( k \) is the key, \( p_1, p_2 \) are constant padding strings, and \( \parallel \) denotes concatenation. This generic construction is called HMAC (hash-based MAC), see Krawczyk, Bellare, and Canetti, 1997 for implementation and security details.

Digital Signatures

MACs are useful for guaranteeing the authenticity of a communication link. However, they do not provide a transferable proof of authorship: As the parties at both ends of the channel share knowledge of the key, a “MACed” message \( (x, h_k(x)) \) could originate from either of them. As a matter of fact, a third party cannot deduce its author. Transferable proofs of authorship are required to model digital workflows, for example orders in electronic commerce that must be verifiable by multiple parties (possibly including a judge in order to arbitrate in a dispute). Digital signature schemes are a means to provide such evidence. They are also implemented with public key cryptography. Signature verification is a one-way function with trapdoor, referring to the ability to create signatures.

The RSA signature scheme is based on the same mathematics as the RSA cryptosystem. Signing corresponds to decryption while verification corresponds to encryption. Digital Signature Algorithm (DSA) and its EC-based variant EC-DSA are alternative schemes which are not yet as prevalent as RSA. EC-DSA is more efficiently computable than RSA and uses shorter keys for comparable strength.

Signatures are, in fact, computed over the hash value \( h(x) \), not the message \( x \) itself. One reason is the reduction of computational costs associated with public key cryptography. Secondly, the one-way property of the hash function prevents so-called existential forgery of signatures (see e.g., Buchmann, 2004). However, \( h \) must be collision-resistant as in the case where \( h(x) = h(x') \), a signature of \( x \) is always a signature of \( x' \), too.

Messages that comprise declarations of intent should be legally binding for the originator. On the one hand, this implies that the originator commits himself to the content in a way that he cannot deny his intent later. On the other hand, no one other than the legitimate person should be able to
make a commitment in his name. This property is called non-repudiation. Non-repudiation can be achieved with the help of dedicated hardware, for example a smartcard or TPM (Trusted Platform Module, see e.g., Eckert, 2006) chip that keeps the signing key under the sole control of its owner.

Observe that deniability, the opposite of non-repudiation, may indeed be a desirable security goal sometimes, for instance in order to cope with censorship in UC networks. In such a setting, MACing should be preferred to signing of messages.

Hybrid Encryption and Key Exchange

In practice, asymmetric and symmetric cryptosystems are combined in hybrid encryption in the following way: Symmetric cryptosystems typically have a much higher throughput compared to public key systems with a comparable security level. Therefore Alice first encrypts the plaintext with a symmetric cryptosystem using a random, ephemeral session or transaction key. Then she transmits the symmetric key to Bob in a confidential way by encrypting it with his public key (if the message has multiple recipients, they all obtain the same ciphertext accompanied by the same symmetric key encrypted with their individual public key). The mechanism of distributing key material is called key exchange. The term key agreement is often used synonymously, but may sometimes emphasize the fact that both parties contribute to the generation of the key. The Diffie-Hellman (DH) protocol is the most famous interactive key exchange scheme. It allows two parties linked by an authentic, but not necessarily private, channel to agree on a common secret—which seems counter-intuitive at first sight. Note that unauthenticated DH is inherently prone to MITM attacks. Authenticated DH can be implemented by having each party digitally sign its protocol messages. The mathematics and security properties of DH are closely related to the ElGamal cryptosystem.

An authentic key agreement protocol like the DH scheme allows parties to achieve forward secrecy, that is, to limit the possible impact of a broken key: If a long-term signing key falls into Mallory’s hand, this does not leak the plaintext of past communications Mallory may have recorded. On the other hand, a broken ephemeral symmetric key only affects the particular messages encrypted with it. Forward secrecy allows the parties to use relatively short symmetric keys provided they are changed frequently. When this trade-off is made in a UC scenario, the cost reduction for symmetric encryption due to smaller key sizes has to be balanced against the overhead for key exchange.

Potential and Limitations of Cryptography in UC

Having outlined the general tools of cryptography, we conclude this section by a discussion of computational costs. Since energy consumption is a serious issue in UC, we direct the reader’s attention to Table 3. These figures are the outcomes of experiments with a 206 MHz Compaq iPAQ H3670 described by Potlapally, Ravi, Raghunathan, and Jha (2003). The table shows the setup and current costs for the families of algorithms we explained above. Observe that the costs of hashing and symmetric encryption are given in μJ, whereas mJ is the unit for digital signatures.

Due to its output size of only 128-bit, we included the hash function MD5 for comparison although its use is no longer recommended. The figures for the AES algorithm refer to the standard operation mode CBC (see e.g., Buchmann, 2004). AES is a so-called iterative block cipher. Its computation is organized in multiple rounds implementing the same subroutines, but with different round keys. The round keys are derived from the actual (128, 192, or 256 bit) key. This process is called key scheduling.
The table shows the signature algorithms RSA, DSA, and EC-DSA with their respective security parameters. These three combinations are considered of having comparable strength. While the costs for the respective setup do not differ too much, the costs for signing and signature verification vary significantly. Obviously, EC-DSA is a better choice than DSA as each operation is cheaper. However, the choice between RSA and EC-DSA is determined by the expected number of operations of the UC system. If the number of signature verifications compared to signature generations dominates, the RSA signature scheme is clearly favorable compared to EC-DSA.

However, concerning key exchange, EC-DH definitely outperforms standard DH (where computations are done in $\mathbb{Z}/\mathbb{Z}_p$) with the same security level. In order to achieve roughly the same costs as EC-DH, DH keys must be restricted to 512 bits in length.

We have not mentioned asymmetric encryption so far. Since the same mathematical formula is used for the RSA cryptosystem and the RSA signature scheme, the corresponding numbers can be looked up in the table. This shows that in some UC situations with constrained devices, asymmetric cryptosystems may quickly become impractical while symmetric encryption is cheaper by magnitudes. Contemporary public key algorithms are not very well suited for the capabilities and needs of UC (Buchmann, May, & Vollmer, 2006). A back-of-the-envelope calcula-
tion shows that a pocket PC’s battery with a 1500 mAh capacity and a 5V voltage would have lost 20% of its charge after 5000 executions of a DH protocol or 10000 RSA signatures.

These facts illustrate that it is worthwhile to precisely analyze the security demands of a UC system since choices on the cryptographic layer directly affect energy consumption. A comprehensive examination of energy costs is provided by Seys (2006). Lightweight UC cryptography has also been the subject of recent research activities, for example, by the ECRYPT Network of Excellence in Cryptology (http://www.ecrypt.eu.org). This issue will surely gain even more momentum with the deployment of RFID tags for industrial applications as we already sketched in Scenario 4.

Lightweight cryptography has several aspects. On the one hand, it comprises the design choice of algorithms and efficient engineering to implement them in hard- and software. On the other hand, it requires a re-assessment of the threat model by assuming a less powerful opponent and ruling out some particular attacks which are considered less likely. This may imply that weaker security mechanisms, like weak authentication (discussed next), or lower security parameters are acceptable for low-value transactions (cf. the discussion of forward secrecy).

Cryptography offers a wealth of ideas that can be applied to UC: For instance, traditional protocols can be enhanced to provide privacy protection using mechanisms like the private authentication scheme explained below. We also point out that threshold cryptography (see for example, Gemmell (1997) for an introduction) is a valuable tool for UC that merits further study. For instance, it can be used in sensor networks that are prone to so-called Byzantine faults, that is, there is a risk that devices fall into the attacker’s hands and then act incorrectly. Provided that the number of such “Byzantine” nodes is lower than an adjustable bound, the attacker learns nothing about a secret (e.g., a common key for signing responses) shared among the nodes. Interestingly, this statement holds in an unconditional sense, that is, for an adversary with unlimited computational power.

**SAMPLE SOLUTIONS**

In this section five example solutions for secure UC systems are described. References to the literature and UC applications as well as links to our scenarios are given in the text.

At first, we present two strategies of privacy-enhancing technologies: the technical concept of anonymity and a policy-driven approach. While anonymity is favorable from a privacy perspective, it nevertheless leads to new threats as malicious parties may benefit from it, too. One such threat is the so-called Sybil attack which is discussed in the section “Fighting Sybil and DoS Attacks”. We explain the technique of proof-of-work as a countermeasure which can also be used as a defense against DoS. A typical situation in UC is the lack of a priori trust relations among the participants. In order to cope with such a setting, a secure communication channel has to be bootstrapped somehow. The section “Bootstrapping Secure Communication” treats this aspect from a theoretical point of view. Above all, the resurrecting duckling security policy model is explained here. The following section gives several real-world examples for out-of-band channels used to set up secure UC communication. Finally we touch on the hot topic of RFID security and discuss in particular privacy concerns and protection mechanisms of electronic travel documents.

We deliberately omitted reputation systems from the set of examples, as this topic is the subject of the following chapter. Trusted Computing is also an interesting direction of current UC research, but would go beyond the scope of this chapter. We refer the interested reader to the work of Hohl and Zugenmaier (2005).
Privacy-Enhancing Technologies

A large number of UC environments rely on sensing and tracking technologies of users and devices in order to carry out their tasks. For example, in order to provide location-based services, a user’s position has to be determined beforehand. But even without a given UC service in place, the fact that most communication takes place over a wireless link opens the door for attacks based on traffic analysis. All communication patterns that can be successfully linked to a human jeopardize a user’s privacy. In this sense, the notion of confidentiality has to be extended to message source confidentiality and/or message destination confidentiality. This property of hiding the fact that particular communication relationships exist at all is also called sender or recipient anonymity, respectively. Anonymity is significantly more difficult to achieve than message content confidentiality, as it requires careful design of communication protocols. Examples in the Internet setting include mix networks (Chaum, 1981), onion routing (see http://tor.eff.org for a popular implementation), or anonymous re-mailers. Those protocols however cannot be directly adapted to the UC world, since they typically make assumptions about connectivity and resources. A first step in this direction is the idea of “Mist Routing” (Al-Muhtadi, Campbell, Kapadia, Mickunas, & Yi, 2002). “Mix Zones” are a variant of the concept of mix networks to locations (see Beresford & Stajano, 2004).

As mentioned before, anonymity is of particular interest in UC when it comes to achieving location privacy, that is, to prevent people bearing devices emitting radio signals from being tracked without noticing it. We discuss two different strategies to preserve a user’s privacy. First, a number of technical means are presented in order to blur data that could later be used to identify a person/subject. Second, the policy-based approach to achieve user privacy as proposed by Langheinrich (2002).

Blurring Data

Gruteser and Grunwald (2003) propose a middleware-based approach to blur location information from clients before passing the location information onwards to a location-based service provider. They assume that clients communicate their position as very precise location information to a location server. Position is determined on the client itself, for example, via GPS or by the wireless service provider through signal triangulation. Location-based service providers access location information through the location server (see Figure 1).

A client specifies that he wants to be indistinguishable from at least \( k - 1 \) other clients within a given area and time frame. In other words, the clients want to stay \( k \)-anonymous. To reach \( k \)-anonymity, their algorithm, an adaptive form of a quadtree-based algorithm, adjusts the resolution of location information along spatial and temporal dimensions in order to meet the specified anonymity constraints, say \( k \).

Providing anonymity requires careful system design as identification may happen on each network layer (Avoine & Oechslin, 2005). As a

Figure 1. Anonymizing middleware for location-based services
practical consequence, user-controlled pseudonyms on the application layer are pretty useless if the devices itself can be re-identified. This is the case when static IP or Media Access Control addresses are used. A proposal for temporary addresses for anonymity on the data link layer is made in Orava, Haverinen, and Honkanen (2002). UC environments like scenario 2 are particularly suitable for addresses that are picked at random, since the number of devices that are connected to each other at the same time is by magnitudes smaller than in an Internet setting. This guarantees, with a high probability, that device addresses do not coincide.

Private Authentication

The following example illustrates how cryptographic protocols can be modified to provide location privacy on the application layer. In typical schemes for mutual authentication like the one used in TLS/SSL (Dierks & Rescorla, 2006), the parties reveal their identity during the handshake. As a consequence, Mallory may pretend to be a legitimate party and start a handshake in order to see who is in her vicinity. She may also eavesdrop while Alice and Bob are authenticating each other and learn about their communication relation. Private authentication tackles this problem. The approach of Abadi (2002) allows Alice to prove her identity to some self-chosen set \( S \) of peers in order to establish a private and mutually authenticated channel. Entities outside of \( S \) cannot detect Alice’s presence while entities inside \( S \) do not learn more than their own membership. Without loss of generalization, we restrict ourselves to the case where Bob is the only member of \( S \). If the set \( S \) contains more than one element, Alice simply goes through parallel executions of the protocol for each element. In order to start a communication with Bob, Alice broadcasts the plaintext “hello” accompanied with

\[
 c := \text{Enc}_{K_B}(\text{“hello” ||} K_A || \text{Sig}_{K_A^{-1}}(K_A || K_B || K || t) ).
\]

Here \( K_B \) is Bob’s public key used for encryption, \((K_A,K_A^{-1})\) denotes her own key pair, \( K \) a session key, and \( t \) is a timestamp. As Bob is the only entity who knows the private key \( K_B^{-1} \), he is able to extract from \( c \) the sender’s identity (which is unforgeable due to the digital signature). Assuming that Alice is on his whitelist of peers, he answers with a message protected by \( K \). Bob’s presence in turn cannot be detected provided that the cryptosystem is which-key concealing (i.e., \( K_B \) cannot be deduced from \( c \)) and Bob ensures \( t \)’s recency. Otherwise Mallory could mount a replay attack by sending \( c \) and checking whether there is a corresponding answer. Abadi (2002) also describes a second protocol without timestamps at the price of additional communication rounds. This variant might be useful in cases where one cannot assume synchronized clocks.

A Policy-Based Mechanism

Langheinrich (2002) proposes pawS, a system that provides users with a privacy enabling technology. This approach is based on the Platform for Privacy Preferences Project (P3P, see http://www.w3.org/TR/P3P/), a framework which enables the encoding of privacy policies into machine-readable XML. Making use of a trusted device, the so-called privacy assistant (PA), the user negotiates his privacy preferences with the UC environment. For this purpose, the PA is able to detect a privacy beacon upon entering a UC environment, for example, a smart space. The privacy beacon announces the available services, for example, a printer, or a video camera, with a reference to their data collection capabilities and policies. The PA in turn contacts the user’s personal privacy proxy located on the Internet, which contacts the corresponding service proxies.
Security for Ubiquitous Computing

at their advertised addresses (through the privacy beacon) and asks for the privacy policies of the services located in the smart space. These privacy policies are compared to the user’s privacy preferences and a result may be to decline usage of a tracking service, which will result in disabling a video camera. Further, the work of Langheinrich (2001) includes four design principles for UC environments, the main ideas of which we sum up as follows:

- **Notice**: Since future UC environments will be ideally suited for unnoticed operation, monitoring and tracking, the author proposes some kind of announcement mechanism that allows users to notice the data collection capabilities in their environment. This announcement mechanism should be standardized and agreed on.

- **Choice and consent**: To preserve privacy, a future UC system should offer users the choice of allowing or denying any kind of data collection. A system should respect this choice and operate only on user consent. Since a user will not always explicitly express her will, her choice and the derived consent should be expressed in machine-readable policies.

- **Proximity and locality**: Locality information for collected data should be used by the system to enforce access restriction. This restriction may be based on the location of a user who wants to use the data, for example, a user is able to record an audio stream at a meeting while attending, but not from the opposite side of the world (proximity). Also the audio stream should not be disseminated through the network (locality). This idea is also present in location-limited channels and location-based authentication (see below).

- **Access and recourse**: A system should give users easy access to collected personal information (e.g., using a standardized interface). Also, they should be informed about any usage of their data. Thus, abuse would be noticed.

Following these principles, Langheinrich’s goal is to allow people and systems which want to respect a user’s privacy to behave in such a way. This should help in building a lasting relationship based on mutual trust and respect. However his goal is not to try to provide perfect protection for personal information that is hardly achievable anyway.

**Fighting Sybil and DoS Attacks**

As mentioned in the section “First View: UC Characteristics and Associated Risks”, DoS may be a serious attack in UC. In a world of widely-deployed pervasive computing devices, a phenomenon comparable to unsolicited email as we experience it today in the Internet setting would be disastrous. In this section we describe a mechanism that can be use as a remedy for DoS attacks and for so-called Sybil attacks as well (see Levine, Shields, and Margolin (2006) for an overview). The latter are an inherent threat to recommender or reputation systems, which are the subject of the following chapter. The term Sybil stems from the name of a schizophrenic literary character that has a total of 16 personalities. Analogously, an attacker takes part in a recommender system under multiple identities in order to manipulate the trustworthiness rating of nodes. DoS and Sybil attacks have some similar characteristics which is why they are jointly dealt with in this section.

In a setting where UC nodes can be identified in a reliable way, the risks for both attacks are quite low. Clearly, a necessary condition for a Sybil attack is a node’s ability to remain anonymous. In the DoS case, illegitimate messages can be filtered out by so-called whitelists and blacklists containing accepted and non-accepted entities, respectively. Filtering in its turn can be done on each network layer provided the sender...
In the following example we sketch a mechanism that is similar to the one applied by Hashcash (Back, 1997). Here, the challenge is time-dependent. The proof of work consists of partially inverting a one-way hash function \( h \) by brute-force search. The sender of a message has to find a solution \( X \) to the following equation:

\[
\text{hash} (\text{id} \ || \ t \ || \ X) = 0 \ldots 0 \quad \text{\( \ell \)-times}
\]

Here, \( \text{id} \) is the recipient’s identifier (e.g., a pseudonym), \( t \) is a time stamp and \( h \) is the output of \( h \) shortened to the leading \( \ell \) bits. The tuple \((\text{id}, t, X)\) is sent along with the payload. The following checks are made at the receiver’s side: At first, she checks whether \( \text{id} \) is her own ID and whether the message is suitably recent, that is, \( t \) differs less than a predefined clock skew bound of \( s \) seconds from her local time. Furthermore the above condition must hold. In order to prevent a PoW from being reused, \((t, X)\) can be checked for freshness against a database that caches previous values for \( s \) seconds.

The sender has to try out \( 2^\ell \) possibilities for \( X \) on average, until a solution is found. This implies that the sender has to invoke the hash function \( 2^\ell \) as many times as the recipient. The complexity for the sender grows exponentially in \( \ell \). Depending on the performance of the devices in use, \( \ell \) should be adjusted in a range of, say, 10–20 in practice.

We will revert to the concept of PoW in the following chapter in the context of micropayment schemes.

**Bootstrapping Secure Communication**

Consider the situation where two UC devices want to establish a secure communication channel between each other in the presence of an adversary. Here secure may have the meaning of confidentiality and/or authenticity. As confidentiality is
Achieved by encryption, the parties have to secretly agree on a shared key or exchange their public encryption keys in an authentic way—depending on whether they use a symmetric or asymmetric cryptosystem. The requirements for authenticity are quite similar: a MAC key has to remain secret as well and the public key for the verification of a digital signature has to be authentic.

The bootstrapping of a secure channel thus boils down to either initially obtaining some information in a confidential or authentic way. Observe that, by using public key cryptography, an authentic communication relation can be enhanced to an encrypted one. If there is no (common) central authority like a certification authority or a key distribution center the devices have a trust relation with, they have to resort to direct exchange of cryptographic information via so-called out-of-band communication. This is a well-known concept which is applied, for instance, in the context of secret key distribution by messengers or the verification of public key fingerprints on the phone.

Out-of-band communication requires a secondary link, typically with some technical limitations, but with the huge advantage of being safe from attacks. Such limitations, that make this secondary channel unattractive for general data transfer, include bandwidth, signal strength, error rate, latency, and so forth. What is typically considered a downside simultaneously reduces the risk of attacks on this channel. Balfanz, Smetters, Stewart, and Wong (2002) use the term of location-limited channels and emphasize that humans can be in control of the communication links. These authors assume an authentic out-of-band communication channel while the resurrecting duckling security policy model by Stajano and Anderson (1999) requires a confidential one. Stajano and Anderson use a confidential channel in order to securely pair mobile devices for a certain period of time; they use the term secure transient association. We will discuss their model in greater detail now.

Secure transient association addresses the problem of device authentication in the absence of a central and always available authority, for example a public key infrastructure. Devices authenticate each other and agree upon a shared key by physical contact. For a user, physical contact has the advantage that it is simple to understand and it is clear which devices are involved in the paring. The two devices take different roles:

- A slave (or duckling) obeys a master
- A master (or mother duck) controls a slave

Initially the slave is in state imprintable. As soon as a master has sent a key to the slave—this process is called imprinting—via a physical contact, the slave follows commands only given by the master who owns the key. The slave is now in the state imprinted.

The association can be broken in three ways. First, the master sends a special kill command to the slave. The slave will reset itself into the initial state imprintable. Second, after a predefined time interval has gone by, the slave kills itself. And third, after the completion of a certain transaction, the slave will reset itself to imprintable.

The two states of a slave and its transition are depicted in Figure 2. Note that the slave needs to be constructed in a tamper resistant manner. This guarantees that it is uneconomical for an attacker to attack by artificially causing a slave to die, that is, to force a slave into state imprintable. Otherwise, this would allow an attacker to imprint the slave using its own key and gain control over the slave. We quote Stajano’s four formal principles that make up the resurrecting duckling security policy (Stajano, 2002):

1. **Two state principle:** The entity that the policy protects, called the duckling, can be in one of two states: imprintable or imprinted. In the imprintable state, anyone can take it over. In the imprinted state, it only obeys its mother duck.
2. **Imprinting principle:** The transition from imprintable to imprinted, known as imprinting, happens when a principal, from then on known as the mother duck, sends an imprinting key to the duckling. This must be done using a channel whose confidentiality and integrity are adequately protected. As part of the transaction, the mother duck must also create an appropriate backup of the imprinting key.

3. **Death principle:** The transition from imprinted to imprintable is known as death. It may occur under a very specific circumstance, defined by the particular variant of the resurrecting duckling policy model that one has chosen. Allowable circumstances, each corresponding to a different variant of the policy, include:
   - Death by order of the mother duck.
   - Death by old age after a predefined time interval.
   - Death on completion of a specific transaction.

4. **Assassination principle:** The duckling must be constructed in such a way that it will be uneconomical for an attacker to assassinate it, that is, to cause the duckling’s death artificially in circumstances other than the one prescribed by the Death principle of the policy.

An appropriate key backup of the imprinting key is necessary in order to keep control of the slave in case the master is broken. Coming back to the patient monitoring scenario from the section “Four UC Settings”, the resurrecting duckling security policy works for secure transient pairing of a heartbeat monitor with a patient’s record. Here, the record takes the role of the master and the heartbeat monitor the role of the slave. Being at first in an **imprintable** state, as soon as the heartbeat monitor is attached to the patient, it is also imprinted by the patient’s record. Being imprinted, only the master is able to read the heartbeat and store it in the record. As soon as the patient is fully recovered and leaves the hospital, the patient’s record sends a kill command to the heartbeat monitor. The pairing is broken and the monitor is available for another patient.

### Out-of-Band Channels

Many communication technologies are found in the UC world that are suitable for cryptographic out-of-band transmission. We now give a non-exhaustive list of examples that have been already used in practice. Usually switching to a secondary channel requires some human intervention, but may also be triggered automatically by an appropriate protocol command on the primary channel. McCune, Perrig, and Reiter (2005) provide
a comparison of different out-of-band channels with respect to their security, convenience, and hardware requirements.

• **Infrared light** is used in IrDA interfaces for data transmission. It requires a direct line of sight and distances of 1 meter or less between the communicating parties. The salesman from the first scenario may use IrDA to establish a secure connection to a printer by exchanging a short-lived symmetric session key for the next print job or alternatively go through a pre-authentication protocol based on public key cryptography (like in Balfanz, Smetters, Stewart, & Wong (2002)). The idea of an IrDA-based “magic wand” that can be used to point to a device for establishing a secure connection is described by Spahic, Kreutzer, Kähmer, and Chandratilleke (2005).

• Dynamically generated **2D barcodes** can encode about 50-100 bits of information. They are suitable for modern mobile phones, which have high-resolution displays and built-in cameras. Claycomb and Shin (2006) have recently shown how to use colorized barcodes to exchange a public key fingerprint with an application to secure communications with ATMs. The authentication of an 802.11 access point using a sticker with a barcode on its casing is described in McCune, Perrig, and Reiter (2005).

• Devices that have a speaker and a microphone could use **audio** to transfer a fingerprint modulated on a piece of music. While the diffusion of the signal is larger than in the case of infrared, the presence of a second audio sender can be detected by a human. This technology is also suitable for **location-based authentication** of devices. An example is a café rewarding customers with media downloads by distributing access keys for the service via music played inside the building (Coulouris, Dollimore, & Kindberg, 2005).

• Buhan, Doumen, Hartel, and Veldhuis (2006) propose a user-friendly, two-party key agreement protocol that takes as an input **biometric data** of the device owners obtained via a grip pattern sensor. A downside of this approach, however, is the fact that biometric templates are static information and become useless once they fall into an opponent’s hands.

• Capkun and Cagalj (2006) apply **ultrasonic** to measure the distance and spatial direction of UC communication partners. Their concept of **integrity regions** forces the attacker to be physically close to the targets. When devices are operated by humans and the maximum distance is appropriately short, say 1 meter or less, the presence of a man-in-the-middle can be ruled out. Mayrhofer and Gellersen (2007) show how to transmit short messages over ultrasound in such a way that only a recipient at an expected distance from the sender can decode the signal.

• UC devices that do not support any of the above mechanisms, but have at least a **user interface**, can let the user enter a sequence of numbers by hand. Bluetooth applies an algorithm called “pairing” that allows two devices to agree on a common secret key derived from a random value (transmitted in the clear) and a static PIN (typically only a few characters long) that has to be known to each device.

• Even a simple user interface consisting, for instance, of an LED and a pushbutton is enough to transmit 1 bit of information telling the device that it is now safe to exchange public keys via the primary channel. This may happen when the devices are connected in an environment that is considered safe, for example at the user’s home.
The last example is an application of weak authentication as described by Arkko and Nikander (2002). According to the temporal separation principle, at a certain point in time the parties consider safe they exchange a key via the primary channel—without further protection, that is unauthenticated and in plaintext. Provided that no attacker is present in this phase, a long-term secure communication channel can be set up. The weak authentication mechanism completely defeats passive attacks (by exchanging public keys in an authentic fashion). It also raises the bar for active attacks, since a man in the middle who engaged during key agreement has to intercept and re-encrypt each subsequent message in order to remain undetected. A similar mechanism is used in the Secure Shell (SSH) protocol.

**RFID Security from EPC to E-Passport**

In this section the security of RFID systems is discussed, mainly by means of two examples: tags with a 96 bit Electronic Product Code (EPC) are used for the lifecycle management of commercial goods as described in Scenario 4. Such tags are at the lower end of the scale since they offer very limited functionality. At the other extreme, tags embedded in modern identity cards or e-passports (electronic passports) support state-of-the-art cryptographic algorithms.

The threat of abusive tracking of UC systems in general and RFID tags in particular has already been mentioned. Basically, tracking is what EPC tags are built for: Unlike barcodes, they do not simply indicate the manufacturer and product type, but a serial number that is distinct for each object. As access control and reader authentication is only an option in the EPC standards (see http://www.epcglobalinc.org), tags are inherently prone to skimming. That means that unauthorized parties reasonably close may read the chip without its owner noticing it. In the case of EPC tags that operate at a frequency of around 900 MHz, the specified reading range is 3 meters or more. E-passports use so-called proximity tags operating at a frequency of 13.56 MHz and a reading range of at most 15 cm. Note that fraudulent RFID readers do not necessarily adhere to standards and may therefore exceed reading ranges significantly (see e.g., Kirschenbaum & Wool, 2006).

**Countermeasures Against Skimming and Tracking**

EPC tags illustrate a common limitation of most RFID chips: Their identifier is defined during the production process and cannot be changed afterwards. This allows a tagged object to be misused for tracking a person it is linked to. In the discussion of anonymity in the section “Privacy-Enhancing Technologies”, we have already seen that identification is a problem affecting all network layers. RFID systems are no different in that respect as tracking may in theory happen on the application, the data link, or the physical layer. Consider, for instance, tags used in access control systems like the Hitag, Legic, or Mifare series. In order to prevent cloning and replay attacks, such tags may encrypt their communication on the application level. While this hides personal information of their owner, the tags themselves can be easily traced using their static data link layer ID.

In the EPC system, there is at least a basic, yet very effective privacy protection mechanism: A reader may send a tag the so-called “kill” command rendering it irreversibly inoperable. In order to prevent DoS attacks, the kill command requires authentication via a secret 32-bit number. The METRO group’s vision of an RFID-based store (see http://www.future-store.org) already encompasses a dedicated device behind the cash desk to kill tags. However, this comes at the price of excluding the tag ID from being used by the consumer at her home or for the purpose of recycling.
There are several non-destructive countermeasures against skimming and tracking, for a comparison see for example, Weis, Sarma, Rivest, and Engels (2003) or Juels, Rivest, and Szydlo (2003). For instance, RFID chips in identity cards can be shielded in a Faraday cage made of metal foil which is integrated in a wallet. “Clipped tags” (Karjoth & Moskowitz, 2005) provide a user-friendly way to deactivate a tag by manually separating chip and antenna. Such a method provides immediate visual feedback about the tag’s state. Instead of completely deactivating the tag, the antenna may be transformed in a way that reduces reading range considerably. Blocker tags (Juels et al., 2003) are devices that fool readers by simulating a pile of tags in order to prevent them to single out and communicate with a single one. As the EPC addressing scheme is hierarchical, a blocker tag may restrict the range of IDs selectively.

E-Passport Security Measures

Compared to EPC tags, the tags embedded in e-passports contain information that is much more sensitive. The specifications (ICAO, 2004a, 2004b) for “machine readable travel documents” provided by the International Civil Aviation Organization (ICAO), a United Nations body, govern the storage of personal and especially biometric data on the chip. Mandatory pieces of information include name, date of birth, nationality, and a digitized portrait photograph. While the standard defines iris scans and fingerprints as optional features, the member states of the European Union have agreed on including fingerprints in passports issued to their citizens (European Union, 2006).

As a baseline security mechanism, all e-passports have to implement “passive authentication”. This means that the data stored on the chip is digitally signed by the issuing nation. The signature algorithm may be one of RSA, DSA, or EC-DSA. While passive authentication prevents modifications of the chip, it does not help against chip cloning; only the optional feature “active authentication” does. Here, the chip is given a key pair the public key of which is included in the signed data set. During a challenge-response protocol, the chip proves possession of the private key and therefore its authenticity to the reader. While other chip data can be read and cloned, the private key is not disclosed similarly to a smartcard.

The ICAO specifications offer “Basic Access Control” (BAC) as an optional protection against eavesdropping, skimming, and tracking. When implemented on the chip, a reader is required to authenticate before being able to read non-sensitive data, that is, any information except fingerprints (and iris scans if present) which require additional authentication. EU e-passports implement BAC while US e-passports do not. This opens the door for “American-sniffing bombs” or even personalized RFID-enabled bombs (Juels, Molnar, & Wagner, 2005). The design of the BAC mechanism is guided by the idea that a passport has to be handed over to border control personnel, that is, physical access to the document is a prerequisite to reading the RFID chip. In order to start the communication, a reader must pass a challenge-response protocol with the chip. In this protocol, the reader has to implicitly prove that it knows two cryptographic keys derived from the passport number, the bearer’s date of birth, and the expiration date. These parameters are part of the so-called “Machine Readable Zone” (MRZ) which is why an e-passport has to be swiped through an optical reader first. The keys derived from the MRZ are used for 3DES encryption and integrity protection respectively. Note that, although the 3DES encryption uses a 112-bit key, the entropy obtained from the MRZ is much lower. The number of possible values can be at most \(2^{35}\) in theory, but practical figures may be significantly lower: The feasibility of a brute-force attack on Dutch e-passports, which provide encryption strength of around 35 bit due to their predictable serial numbers, is described
Security for Ubiquitous Computing

by Smith (2006). Note that even strong encryption does not prevent tracking by parties that have read the MRZ once, as the derived keys are static.

Another challenge-response scheme is used to protect the fingerprints on the chip. In this protocol, the chip authenticates the reader in order to decide whether to disclose the fingerprint or not. This mechanism involves national authorities that issue certificates to border control organization of foreign countries upon condition that fingerprints are treated in accordance with data security and protection legislation. These organizations in turn issue certificates to individual readers. A detailed description of the infrastructures used for issuing certificates to passport manufacturers and to readers respectively is given by Straub, Hartl, and Ruppert (2006).

RESEARCH OUTLOOK

This chapter gave an overview of the field of UC security taking into account UC characteristics and limitations. By means of representative settings, ranging from mobile work to RFID-based real-time enterprises, common security challenges were exhibited. At the heart of the chapter was the presentation of a bunch of concrete solutions to such challenges. This list is not claimed to be exhaustive, but it is an initial step toward a taxonomy. The solutions stand pars pro toto for UC security, as they are generic and scalable enough to be adaptable to a large number of scenarios.

Social acceptance of UC technology strongly depends on the security of UC systems. On the one hand, the growing use of UC in everyday life must not lead to security breaches as demonstrated, for instance, in a recent attack on RFID-enabled credit cards (Heydt-Benjamin et al., 2007). It is also a safe bet that conflicts of interest will again occur between privacy and law enforcement as we have already seen in the aftermath of 9/11, for example, concerning the traceability capabilities of UC. We hope that this chapter motivates the reader to delve deeper into the subject and refer to the following textbooks:

• IT security in general: Eckert (2006), Stallings (2006),
• Focus on cryptographic aspects: Buchmann (2004), Stallings (2005); Menezes, Oorschot, and Vanstone (1996),
• UC security in particular: Stajano (2002),
• RFID: Finkenzeller (2003).

Among the promising areas of UC security research we could not discuss in detail here are UC and its relation to Grid Computing (Storz, Friday, & Davies, 2003) and relay attacks on RFID systems (Kfir & Wool, 2005; Hancke 2006).

Section II
Development and Design Methodologies

This section provides in-depth coverage of conceptual architectures, frameworks and methodologies related to the design and implementation of interfaces and technologies that promote successful human-computer interaction. Throughout these contributions, research fundamentals in the discipline are presented and discussed. From broad examinations to specific discussions on particular frameworks and infrastructures, the research found within this section spans the discipline while also offering detailed, specific discussions. Basic designs, as well as abstract developments, are explained within these chapters, and frameworks for designing and personalizing interfaces for medical equipment, televisions, and automobiles are discussed.
Chapter 2.1

Measuring the Human Element in Complex Technologies

Niamh McNamara
University College Cork, Ireland

Jurek Kirakowski
University College Cork, Ireland

ABSTRACT

Measuring satisfaction can provide developers with valuable insight into the usability of a product as perceived by the user. Although such measures are typically included in usability evaluations, it is clear that the concept itself is under-developed. The literature reveals a lack of cumulative, systematic research and consequently the field is in “disarray” (Hornbæk, 2006). Clearly, the area needs a strong theoretical foundation on which to base research. This paper reviews the literature on user satisfaction and proposes a conceptualisation and definition of the concept that will aid researchers in the development of valid measures.

USER SATISFACTION AS A USABILITY PARAMETER

The ISO 9241-11 standard suggests assessing usability in terms of performance by measuring effectiveness and efficiency, and in terms of internal state by measuring satisfaction. It recommends that at least one measure of each parameter should be included in usability evaluations. Despite this, Lindgaard and Dudek (2003, p. 430) have observed that the:

Human-computer interaction literature has traditionally concerned itself almost exclusively with effectiveness and efficiency with satisfaction being regarded (as) mainly a by-product of great usability.

Although satisfaction is a central concept in HCI it has been described as “underdeveloped” (Tractinsky, 2004, p. 352). It is the criterion most often included in usability evaluations (Kirakowski, 2002) but there is little understanding on the part of evaluators of what exactly they are measuring, and often the tools they employ are poorly developed. This article will illustrate the consequences of the lack of a cumulative, systematic approach to research that is evident in the
literature on user satisfaction (Hornbæk, 2006). It will be shown that much of what is known about satisfaction is based on relatively little empirical work and represents opinion rather than fact. The diversity of adjectives used in satisfaction measures is symptomatic of the lack of a cumulative, systematic approach to research in the field. Hornbæk (2006, pp. 90, 91) observes that “comparisons across studies become difficult because of this diversity, as does the understanding of distinct dimensions of subjective satisfaction.”

Clearly, the field needs a theoretical foundation on which to base research beginning with a sound conceptualisation of the construct and a suitable definition.

There are very few definitions of satisfaction to be found in the HCI literature. Possibly the closest the field has to a standard definition is that provided by ISO 9241-11, where satisfaction is defined as “freedom from discomfort and positive attitudes towards the product.” However, this is quite a broad definition that gives little insight into the nature of the satisfaction construct. Although there is no widely-accepted definition, there seems to be a number of common elements that most researchers agree on. Satisfaction is:

1. A response (either cognitive or emotional) on the part of the individual (Chin, Diehl, & Norman, 1988; LaLomia & Sidowski, 1990; Lindgaard & Dudek, 2003)
2. To an interactive system
3. Based on the degree to which the user feels the device facilitates the completion of a particular goal (LaLomia & Sidowski, 1990; Bevan & MacLeod, 1994; Kirakowski, 1999)
4. That is linked to usage (Lund, 2001; Kirakowski, 2002)

These characteristics are similar to those of the attitude construct in social psychology. Indeed, satisfaction is often described in the literature as an attitude (Melone, 1990; Nielsen, 1993; Keinonen, 1998; Shneiderman, 1998). Melone (1990) suggests that conceptualising satisfaction in this way provides the necessary theoretical foundation for research and “retains the essential elements embodied in the user satisfaction construct.”

This article starts by reviewing attempts to measure and uncover the structure of user satisfaction from early HCI, research on Information Systems, and from recent HCI. Checklist approaches to usability in general (e.g., Reiterer & Oppermann, 1993; Ravden & Johnston, 1989) will not be reviewed here as they are too broad in scope; neither will the influential research of Dzida, Herda, and Itzelfeldt (1978) for the same reason. Although each of these approaches creates methods of assessment which involve questionnaires, they only look superficially like satisfaction questionnaires; they are closer to checklists.

The measurement of satisfaction would greatly benefit from the provision of a sound theoretical base for research (Melone, 1990; Hornbæk, 2006). Melone (1990) suggests that this would be best achieved by conceptualising satisfaction as an attitude. Although HCI uses the term attitude regularly in discussions on satisfaction, rarely are the implications of this way of conceptualising satisfaction addressed. This article will go on to illustrate how this conceptualisation does indeed retain satisfaction’s essential elements while also clarifying some theoretical issues facing researchers, specifically (1) determining the nature of the user’s response (i.e., whether it is cognitive or emotional), (2) conceptualising satisfaction as a characteristic of the interaction (quality in use) rather than as a product attribute (quality of features) and (3) understanding the relationship between satisfaction and usage behaviour. Following conceptualisation of satisfaction as an attitude, a definition of the construct in keeping with its character as a usability parameter is offered.

Finally, four proposals are made for the future development of measuring instruments for satisfaction.
UNCOVERING THE STRUCTURE OF USER SATISFACTION

Early Satisfaction Research in HCI

Most of the research on satisfaction was carried out in the context of developing questionnaires to measure user satisfaction during the late 1970s and 1980s. At this time, developers were becoming more aware of the need to evaluate the usability of their products. Various types of questionnaires were developed. Some were single-use instruments constructed for specific studies that often only provided a global measure of satisfaction, while others were developed in industry, such as Brooke’s (1996) system usability scale (which was developed in the 1980s while the author was employed by the Digital Equipment Corporation, DEC) and Lewis’ (1995) IBM usability questionnaires. While instruments like SUS and the IBM questionnaires have proven to be quite useful when evaluating software, they have offered little in the way of progress in understanding the nature of user satisfaction. For this, one has to turn to instruments developed in an academic context. While few such instruments exist, they are worth examining primarily for their efforts to uncover the structure of user satisfaction, and also as a potential starting point for research on user satisfaction with new technology.

The questionnaire for user interface satisfaction (QUIS) (Chin, Diehl, & Norman, 1988) and the computer user satisfaction inventory (CUSI) (Kirakowski & Dillon, 1988) are two early satisfaction questionnaires developed at roughly the same time, but that conceptualised the construct in two different ways.

QUIS, which is still widely used today, was originally constructed to measure “the user’s subjective rating of the human-computer interface” (Chin et al., 1988, p. 213). The authors viewed satisfaction as dependent on system features, and respondents were asked to report their satisfaction with the use of these features on a 9-point scale. The questionnaire had five sections referring to different aspects of the system, namely, Overall Reactions, Screen, Terminology and System Information, Learning, and System Capabilities. Chin et al (1988) carried out a factor analysis on the responses to version 5 of the questionnaire from which they extracted the following four factors: (1) Learning, (2) Terminology and Information Flow, (3) System Output and (4) System Characteristics. Carrying out factor analyses provides an important insight into the nature of a construct, however Chin et al. (1988) did not provide a comprehensive explanation of what the four factors measured. Although they attempted to uncover the underlying structure of satisfaction, the authors failed to provide a meaningful conceptualisation of the construct.

This is in contrast to the development of the Computer User Satisfaction Inventory (CUSI, Kirakowski & Dillon, 1988). This research was informed by Bandura’s (1977) Self-efficacy Theory. Self-efficacy refers to the individual’s belief that he or she can accomplish a particular task. The authors hypothesised that satisfaction could be measured on two dimensions: Affect, which assesses the “(individual’s) feelings of fear or pleasure” and Competence, which assesses the “individual’s feelings of mastery over the computer system” (Kirakowski & Corbett, 1988, p.330). Kirakowski and Dillon (1988) not only created a questionnaire that could be used as an alternative to other more resource- and labour-intensive methods, but also attempted to provide a conceptual understanding of the satisfaction construct.

CUSI includes an affective dimension that is not present in QUIS. While CUSI’s developers did not provide a definition of satisfaction per se, it is clear that they did believe it to contain elements relating to user emotions (Affect) and performance (Competence). This would appear consistent with later definitions of satisfaction such as ISO 9241-11, Bevan and MacLeod (1994) and Bevan and Azuma (1997).
The conceptualisation of usability as *quality in use* in the 1990s greatly influenced research on user satisfaction. Satisfaction was no longer widely regarded as a product property, but as a property of the interaction between the user and the product (Bevan, Kirakowski, & Maissel, 1991). This proved to be a much more successful approach to measuring satisfaction than the previous quality of features approach espoused by Chin et al (1988). Their focus on specific attributes of the product resulted in model instability and limited applicability across applications for questionnaires that followed this route. Thus, attention focused on constructing models of satisfaction that “(attempted) to measure the way the software being rated fulfils some latent need within the user community” (Kirakowski, 1999, p.129).

Examining user reactions to an interactive system applies a psychological approach to the investigation of user satisfaction. The *software usability measurement inventory* (SUMI) (Kirakowski & Corbett, 1993; Porteous, Kirakowski, & Corbett, 1995; Kirakowski, 1996), based on this approach to user satisfaction measurement, has become the *de facto* instrument for evaluating software applications (Kirakowski, 2002). It measures “user-perceived software quality,” which it is hypothesised, consists of five dimensions: Affect, Controllability, Efficiency, Helpfulness and Learnability.

This model has also been successfully applied to the evaluation of user satisfaction with Web sites in the *Website Analysis and MeasureMent Inventory* (WAMMI) (Kirakowski, Claridge, & Whitehand, 1998), illustrating its applicability across technological domains. The five factors of the model were modified slightly for Web sites—the main difference being that the Affect dimension is replaced by an Attractiveness dimension.

We now turn to research on satisfaction from the discipline of management information systems (MIS). While this literature is often included in reviews of user satisfaction research, rarely is it noted that the constructs of *user satisfaction* and *user information satisfaction* are entirely different. The following section will explain these differences and advise caution in borrowing concepts across disciplines.

### Information Systems Research on Satisfaction

HCI and management information systems (MIS) are two disciplines that have a significant interest in assessing satisfaction with technology, and consequently, often cite each other’s research. However, researchers from both disciplines do not seem to recognise the vastly different perspectives each takes on what they perceive to be the same construct, particularly concerning the role of usability in operationalisations and definitions of satisfaction.

The term *user information satisfaction* is itself suggestive of the differences between the ways satisfaction is conceptualised in the HCI and MIS disciplines. MIS is primarily interested in the benefits of technology for decision-making in an organisation and its impact on productivity. The goal of HCI, on the other hand, is to create technology that supports users (Preece, Rogers, Sharp, & Benyon, 1994). The definitions of satisfaction from MIS are broadly similar to ISO 9241-11’s definition of satisfaction. For example, Bailey & Pearson (1983) define it as “the sum of feelings or attitudes, both positive and negative, toward the spectrum of factors affecting a specific situation” (p.531). Similarly, Doll & Torkzadeh (1988) define satisfaction as “the affective attitude towards a specific computer application by someone who interacts with the application directly” (p.261). However, the operationalisations of the construct between MIS and HCI are quite different. Typically, the MIS literature treats usability as one dimension of user satisfaction, while HCI treats satisfaction as a usability parameter. The user information satisfaction construct is influenced by user role rather than conceptualisations of...
usability, while the user satisfaction construct is typically influenced by both. This may be the reason why the usability or ease of use dimension was only included in (MIS) user information satisfaction questionnaires with the advent of end-user computing.

The computing environment and the role of the end-user were undergoing rapid changes during the late 1980s, and with this came a change in the way satisfaction was conceptualised in the MIS literature. Early studies such as those conducted by Bailey & Pearson (1983) and Ives, Olson, and Baroudi (1983) dealt with a system that included the computer, the end-user, and the programmer/analyst. As the end-user became more autonomous, attention was increasingly focused solely on the application, and the output and usability began to be considered. Organisational structures such as EDP personnel were not included in evaluations as prominently as had been the case previously, although some evaluations still included the adequacy of the technical support provided.

A new definition of satisfaction in accordance with these changes was proposed by Doll and Torkzadeh (1988). They defined end-user computing satisfaction as “the affective attitude towards a specific computer application by someone who interacts with the application directly” (p. 261). Doll and Torkzadeh (1988) argued that because the end-user was now interacting with the system directly instead of through programmers or analysts, there was a need to consider the usability (ease of use) of the application. The proposed model, which the authors claimed was more suitable for an end-user computing environment than previous efforts, consisted of five factors, namely Content, Accuracy, Format, Ease of Use, and Timeliness.

Doll and Torkzadeh (1988) did include items referring to ease of use that might lead one to infer that this conceptualisation of end-user computing satisfaction is closer to HCI’s user satisfaction than user information satisfaction. However, this is not the case. Doll & Torkzadeh (1988) still focus on the information product, that is, satisfaction with the information the system provides to the user to assist in decision-making. Furthermore, it seems to oversimplify the concept of usability by simply including the following two items to measure it: “is the system user friendly?” and “is the system easy to use?” (Doll & Torkzadeh, 1988, p. 268). Clearly, these items do not reflect the complexity of the usability construct.

Doll and Torkzadeh’s (1988) end-user computing satisfaction measure became the standard instrument within the MIS community. Much of the research that was conducted after the publication of this questionnaire either involved further validation studies of the instrument or attempts to investigate the relationship between satisfaction and other variables such as usage, user involvement in design, and so on. The research focus shifted from purely measurement issues to theoretical issues, particularly the need to identify the nature of the satisfaction construct and the importance of establishing a sound theoretical base for research. Thus, while the satisfaction construct differs between the two disciplines of MIS and HCI, one thing HCI can and should learn from MIS is the importance of providing a theoretical foundation for research (Melone, 1990).

Recent Approaches to Satisfaction in HCI

Towards the late 1990’s, little further progress had been made in HCI in revealing the true nature of the satisfaction construct. At this time, researchers were becomingly increasingly interested in investigating the wider user experience. There are two emerging approaches to satisfaction research in light of this development.

In the first approach, researchers believe that the satisfaction construct can encompass the wider elements of the user experience (e.g., Han & Hong, 2003; Lindgaard & Dudek, 2003; Yun, Han, Hong, & Kim, 2003), particularly with the
inclusion of new dimensions. The operationalisations proposed by these researchers are very different to those already discussed. For example, Lindgaard and Dudek (2003, p. 430) define satisfaction as an “expression of affect” and suggest it consists of four dimensions: Aesthetics, Likeability, Expectation, & Emotion. Similarly, Yun et al. (2003) define satisfaction as the user’s subjective impression of the device which is informed by performance and emotional aspects. The dimensions of satisfaction they propose include Luxuriousness, Simplicity, Attractiveness, Colourfulness, Texture, Delicacy, Harmoniousness, Salience, Ruggedness, and Overall Satisfaction. Finally, Han and Hong (2003) define satisfaction as meaning that “products should provide pleasure and/or attractiveness” (p.1441). The corresponding dimensions they propose include Volume, Shape, Elegance, Harmoniousness, Simplicity, Comfort, Attractiveness, and Overall Satisfaction. Clearly, these conceptualisations of satisfaction have little to do with perceived usability; rather they refer to aesthetic concerns.

The second approach taken by researchers involves a critique of the relevance of satisfaction. It is argued that the construct should be replaced (Jordan, 1998, 2000; Dillon, 2001). Just like the call to go “beyond usability” (Logan, 1994), Dillon (2001) called for the creation of a construct that goes “beyond satisfaction.” This is because he believed that the concept of satisfaction as it had been understood up to then was inadequate for application to new technology. He proposed the Affect construct as a replacement which is predominantly concerned with user emotions.

Finally, recent approaches to satisfaction are moving from a view of the construct as a characteristic of the interaction to one that conceptualises satisfaction as an intrinsic product attribute. Even though satisfaction has been shown not to be a product characteristic (Kirakowski, 1999), new conceptualisations of satisfaction proposed by Yun et al. (2003) and Han and Hong (2003) take an ergonomic approach and conceptualise satisfaction in terms of product properties. Yun et al. (2003) and Han & Hong (2003) argue that satisfaction is dependent on design. Thus, each of their dimensions consists of particular product properties known as human interface elements (HIEs) that they believe contribute to satisfaction. Using the method of Kansei Engineering, they maintain that it is possible to predict a user’s level of satisfaction with a product before it is released. In doing this, Yun et al. (2003) and Han and Hong (2003) ignore the impact of the context of use on the interaction between the user and the device. Consequently, we see the same difficulties inherent in their approach that were encountered by others who took an ergonomic approach to defining and measuring usability. Before any evaluation could take place using this approach, evaluators would have to ascertain which particular dimensions of satisfaction and which HIEs were relevant to the device under evaluation, making it a time-consuming method, and one that is virtually impossible to apply across devices.

It seems that some researchers are keen to align satisfaction with the concept of experience for no other reason except that it is the only “subjective” construct consistently referred to in the usability literature (Dillon, 2001). However, there is a clear distinction, which is often not made, between the concepts of usability and experience. (This issue is outside the scope of this article; see McNamara and Kirakowski (2005, 2006) for further discussion.)

The satisfaction construct is becoming increasingly broad as is evident in the new definitions and operationalisations of satisfaction that have been proposed in the literature. Indeed, the only common link remaining between recent conceptualisations of satisfaction and earlier ones seems to be that it is still viewed as a multidimensional construct. Unfortunately, there is little theoretical or empirical justification offered as the basis for these new models of satisfaction. Indeed many “new” dimensions appear to be borrowed from other disciplines such as Consumer Psychology.
The absence of clear content boundaries has led to this indiscriminate borrowing of concepts and theories across disciplines.

**What is Satisfaction?**

It is clear from this review of the user satisfaction literature that there are three theoretical challenges facing researchers.

First, little insight is given into the nature of the construct. Some only offer broad definitions of satisfaction and little else (e.g., ISO 9241-11). Others offer both a definition and model of the construct. But in many cases the model does not seem to correspond to the definition. For example, Yun et al. (2003) define satisfaction in terms of both performance and affective elements, yet their operationalisation of the construct does not include any dimensions relating to user performance. Some view the user response as exclusively cognitive (e.g., Chin et al., 1988), others as exclusively emotional (e.g., Han & Hong, 2003; Lindgaard & Dudek, 2003), and still others who take a combined approach including both cognitive and affective elements in their models of satisfaction (e.g. Porteous et al., 1995; Kirakowski et al., 1998).

Second, some researchers view satisfaction as a characteristic of the interaction between the user and the product (e.g. Porteous et al., 1995; Kirakowski et al., 1998) which is in keeping with the quality in use approach to usability proposed in ISO 9241-11 and widely accepted by the majority of usability professionals. However, others view satisfaction as a product attribute (e.g., Chin et al., 1988; Han & Hong, 2003; Yun et al., 2003) indicating a return to the generally discredited quality of features approach to measurement.

Finally, it appears to be taken for granted that satisfaction is linked to usage. Many mention this link (e.g., Lund, 2001; Kirakowski, 2002), but there is little evidence of any investigations (in the HCI literature at least) into the nature of this relationship.

It is unlikely that these issues can be resolved without better theoretical foundations for research. It is argued that conceptualising satisfaction as an attitude can provide such a base (Melone, 1990).

**USER SATISFACTION AS AN ATTITUDE**

The study of attitudes, their structure, formation, and their relationships with other constructs (most notably behaviour) has occupied a central position within Social Psychology almost since its inception (Palmerino, Langer, & McGillis, 1984; Ajzen, 2001).

Although there does not exist a standard definition of attitude (Fishbein & Ajzen, 1975; Dawes & Smith, 1985; Olson & Zanna, 1992), it is clear that evaluation is an important component. This is illustrated in the following four definitions of attitude taken from classics in the attitude literature: (1) “(A term) used to refer to a relatively enduring tendency to respond to someone or something in a way that reflects a positive or negative evaluation of that person or thing” (Manstead, 1996, p. 3); (2) “(a tendency) to evaluate an entity with some degree of favour or disfavour, ordinarily expressed in cognitive, affective, and behavioural responses” (Eagly & Chaiken, 1993, p.155); (3) “a person’s feelings toward and evaluation of some object, person, issue, or event” (Fishbein & Ajzen, 1975, p.12) and finally, (4) “a summary evaluation of a psychological object captured in such attribute dimensions as good-bad, harmful-beneficial, pleasant-unpleasant, and likable-unlikable” (Ajzen, 2001, p. 28).

These definitions demonstrate that theorists define attitudes in affective (e.g., Fishbein & Ajzen, 1975), behavioural (e.g., Manstead, 1996), and cognitive (e.g., Ajzen, 2001) terms. The definition offered by Eagly and Chaiken (1993) where attitudes are defined in terms of all three components (affect, behaviour, and cognition)
represents the most common conceptualisation of attitude structure. Affect refers to the individual’s emotional response to the target of the attitude. Behaviour is the action engaged in by the individual towards the target, which is assumed to reflect the attitude held by the individual. Cognition refers to the knowledge and beliefs held by the individual that link the target to particular attributes.

Definitions of attitude vary because theorists disagree regarding the relative importance of the various processes of affect, behaviour, and cognition involved in attitude formation.

Explaining attitude formation on the basis of affective processes is based primarily on two areas of research: the principles of conditioning, both operant and classical; and, on Zajonc’s (1980) research on the Mere exposure effect. Classical conditioning involves pairing an object with a stimulus that elicits an affective response. Through repeated association, the attitude object comes to elicit the affective response and an attitude is formed. Operant conditioning typically involves reinforcement of positive or negative statements by an individual. The attitude that subsequently forms depends on whether positive or negative statements were reinforced. The mere exposure theory states that familiarity with objects, based on the frequency with which they are encountered, increases liking for those objects.

Bem’s (1972) Self-perception theory is often used to describe attitude formation in terms of behavioural processes. According to this theory, individuals infer their attitudes from their behaviour, that is, engaging in a particular behaviour towards an object (reflecting favour or disfavour) is indicative of their underlying attitude. Bem (1972) states that individuals take context into account when interpreting their own behaviour. Behaviour is seen to be reflective of an underlying attitude only if there are no forces external to the individual that might be inferred to be causing his or her behaviour.

Finally, according to the cognitive perspective, individuals gain information about an object through direct or indirect experience with it. This information results in the formation of beliefs about the object which links it to particular attributes. If the beliefs are mainly favourable, the resulting attitude will be positive, and if the beliefs are mostly unfavourable, a negative attitude towards the object will result.

It seems to make sense to consider satisfaction as an evaluative state that can be formed through any of the affective, behavioural, or cognitive processes. Rather than broadening the construct beyond recognition, it is proposed here that it is best to define it (based on the definition of attitude proposed by Ajzen, 2001) as a summary evaluation of an interactive system captured in terms of how easy the user thinks it is to use. This definition is in keeping with the conceptualisation of satisfaction both as an attitude and as a usability parameter.

Now that a definition of satisfaction has been offered, the ways in which the attitude literature can inform three important theoretical issues facing satisfaction researchers will be discussed: (1) the nature of the user response (i.e. whether it is cognitive or affective-emotional); (2) whether this response is best described as a characteristic of the interaction (quality in use) or as an intrinsic product attribute (quality of features); and (3) understanding the relationship between satisfaction and usage.

The Nature of the User Response

As noted in the review of the user satisfaction literature, some view satisfaction as a cognitive response and others as an emotional response. A minority take a combined view. Consequently, there is a debate as to which view is the correct one. Consumer Psychology typically views satisfaction as an emotional response (Giese & Cote, 2000), and given that this literature has influenced recent operationalisations of user satisfaction, it is no surprise that definitions proposed by Lindgaard and Dudek (2003) and Han and Hong
Measuring the Human Element in Complex Technologies

(2003) have promoted the view of satisfaction as an exclusively emotional response to a product. Some attitude literature in psychology suggests that attitudes can be formed on the basis of emotional processes. Thus, these researchers could point to this literature as providing support for their conceptualisation of satisfaction. However, attitude theorists also do make a clear distinction between affect and emotion, which suggests that satisfaction (or any attitude), cannot be described as simply an emotional response tout court.

There are two ways in which affect, as it is conceptualised by attitude researchers, can be distinguished from general emotions and moods (Judd & Johnson, 1984). First, affect relates to a specific object (Judd & Johnson, 1984; Eiser, 1994). Second, the valence of affect is generally conceptualised as being unidimensional, that is, either positive or negative, while “the more general study of emotions…is full of attempts to invoke more richly defined distinctions” (Judd & Johnson, 1984, p. 66).

This seems to clarify the distinction between viewing satisfaction as an emotional response and viewing it as an attitude that can be formed on the basis of affective processes. However, it does not resolve the issue of which set of processes are primarily responsible for the attitude held by an individual. Is it the affective processes (i.e., the feelings the object elicits) or the cognitive processes (i.e., beliefs about that object)?

Evidence supporting both sides of the debate can be found in the attitude literature. Proponents of the affective perspective argue (in response to the dominant cognitive perspective on attitudes) that affect is more important in attitude formation than cognition because affective aspects are more accessible in memory than cognitive aspects (Ajzen, 2001). Their position is said to be further strengthened by research which states that if there is disagreement between beliefs and feelings, (i.e., if they are of opposite valence), feelings take precedence (Ajzen, 2001).

Proponents of the cognitive perspective, in turn, argue that cognition (specifically awareness) mediates affective processes. Thus, cognitive processes are more influential in forming attitudes than affective processes. Researchers argue that operant conditioning effects are greater when experimental participants are aware of a contingency between responses and reinforcement (Eagly & Chaiken, 1993). Effects of this type are also seen in studies on classical conditioning. Such effects are also seen in research on the mere exposure effect in that participants may be aware that they should respond in a particular way to stimuli that occur more frequently than others. However, there is research involving subliminal presentation of stimuli that produced both conditioning and mere exposure effects. This suggests that conscious stimulus recognition is not necessary for positive attitudes to form toward objects (Eagly & Chaiken, 1993).

Eagly and Chaiken (1993, p. 421) note that there is “a lack of clear criteria to distinguish between affective and cognitive explanations” of attitude formation. For example, some learning theorists believe that it is not responses that are learned in instances of classical conditioning, but mental representations of relationships between stimuli and responses. The authors maintain it is somewhat misleading to refer to conditioning as involving purely affective mechanisms; cognitive processes, they say, can also be used to explain the effects of classical conditioning. According to the principles of classical conditioning, conditioned responses occur automatically in the presence of a conditioned stimulus, that is, they are not mediated by cognitive processes. However, Eagly and Chaiken (1993) argue that associative network models of memory can provide an alternative explanation for why these responses occur. This theory states that each object and each response is represented by a concept node and an evaluative node, respectively, in memory, and that these are linked by an associative bond. A conditioned stimulus (also represented by a concept node)
that is not originally linked with the response becomes linked with it through repeated association. A network is formed between all the concept and evaluative nodes. Activating any one node activates the entire network. It is in this manner that attitudes are formed. Clearly, when the same process can be explained using appeals to both affective and cognitive mechanisms, it is difficult to determine which explanation is correct.

Ajzen (2001, p. 29) notes, “The debate over the cognitive versus affective basis of attitudes has yet to be resolved.” So it seems most prudent to follow a research strategy in which attitudes are hypothesised to form as a result of both affective and cognitive processes (Judd & Johnson, 1984; Ajzen, 2001) rather than either one or the other. The relationship between these two components should be characterised as one of “reciprocal causality” (Judd & Johnson, 1984, p. 79). For example, objects that elicit more intense affect are more easily remembered and judged more quickly than those that elicit less intense affect. In addition, affective responses influence how the individual organises and stores information (Judd & Johnson, 1984).

The implication of this discussion for research on user satisfaction is that it is inappropriate to conceptualise the satisfaction construct as an “expression of affect” where affect denotes emotion only. However, conceptualising satisfaction as an attitude does not preclude the possibility of an affective component considering the reciprocal relationship between affect and cognition.

**Satisfaction: Quality in Use or Quality of Features?**

The second issue facing satisfaction researchers that could benefit from application of theories from the attitude literature is whether it is best to view the construct as a characteristic of the interaction between the user and the product or as a product attribute. As mentioned earlier, it is widely accepted that usability is best conceptualised as a characteristic of the interaction. Given that satisfaction is a usability parameter, one could assume that it also would be conceptualised in a similar manner. However, recent approaches to investigating the construct have proposed a return to the widely discredited quality of features approach. “Quality of features” implies that the level of user satisfaction is dependent on product features (e.g., Han & Hong, 2003; Yun et al., 2003). This approach, referred to very insightfully as “design reductionism” by Hassenzahl, Beu and Burmester (2001), is unlikely to prove successful. Desmet and Hekkert (2002, p. 67) assert that there is not a direct relationship between emotion and product design, and that “emotions are not elicited by product characteristics as such, but by construals based on these characteristics.”

A similar issue arose in the attitude literature. Research on attitudes often neglected the fact that attitudes are social constructs, and instead, they were generally conceptualised as individual attributes (Manstead, 1996). However, newer conceptualisations of attitude argue for the inclusion of context, a variable not often considered in the literature, but which has a significant bearing on attitudes (Palmerino, Langer, & McGillis, 1984; Ajzen, 2001). It is suggested that context may condition attitude (Ajzen, 2001.)

Palmerino et al. (1984, p. 181) define an attitude as “a relationship between two entities where one entity is a person and the other is a person or object” and point out that “the form of this relationship (i.e., the attitude) can be radically different given different contexts” (p.179).

The conceptualisation of attitude proposed by Palmerino et al. (1984) seems well suited to user satisfaction research for two reasons. First, because of the inclusion of context and second, because it views attitude as the relationship between an individual and a psychological object, rather than hypothesising that the attitude resides totally in the person or (absurdly) totally in the object. This bears a striking similarity to the notion of _quality in use_ where usability is conceptualised...
as a property of the interaction between the individual and the device under evaluation.

This discussion suggests that viewing satisfaction as a product characteristic is inadequate (which is what is implied by Yun et al., 2003, and Han & Hong, 2003). Attitude research studies provide the necessary theoretical basis for proposing that satisfaction is a characteristic of the interaction, and support an approach such as that followed by Porteous et al. (1995) which focuses on user reactions to the product rather than referring to specific product features.

**Investigating the Relationship between Satisfaction and Behaviour**

Satisfaction is considered to be an important indicator of future user behaviour (Kirakowski, 2002). However, there is little empirical evidence available to support this claim. Although Melone (1990) cautioned that attitudes only may play a moderating role in determining behaviour, researchers tend to oversimplify the relationship between satisfaction and usage.

It was thought that knowledge of an individual’s attitude could be used to predict his or her behaviour (see the discussion in Eiser, 1994). However, when studies by LaPiere (1934), DeFleur and Westie (1958), and Wicker (1969) found there to be little or no correlation between verbal expressions of attitude and overt behaviour, many called for the abandonment of research into the attitude construct altogether. Fishbein and Ajzen (1975) maintain that poor correlations between measures of attitude and overt behaviours were a consequence of the flawed attempt to predict specific behaviours using general measures of attitude. They developed their own attitude framework. This was an attempt to standardise the terminology used, and to clarify the relationships between the various hypothesised components of the attitude construct and the relationships of the attitude construct itself with other constructs. Fishbein and Ajzen (1975) maintain that the concepts of beliefs, attitude, intention, and behaviour have been used interchangeably in the literature, but by making distinctions between them, many of the inconsistencies found in research on attitudes can be reduced.

In their Theory of Reasoned Action, Fishbein and Ajzen (1975) contend that beliefs are the “fundamental building blocks” that determine attitudes. Intentions are a function of the beliefs the individual has about the behaviour in question, that is, the consequences of performing a specific behaviour and the individual’s evaluation of those consequences. Whether the individual performs the behaviour in question depends on his or her behavioural intentions, which in turn are determined by both the individual’s belief structure and what Fishbein and Ajzen (1975) term the subjective norm: “this refers to the extent to which you believe that your acting in a given way will earn the approval or disapproval of other people whose opinions you value” (Eiser, 1994, p. 21).

In the end, the Theory of Reasoned Action provides a good justification for proposing that satisfaction by itself may never be sufficient to predict behaviour. However, through the Affective route, attitudes must surely influence behaviour and, therefore, we will expect to see a broad degree of relationship between the two. The hypothesis is, therefore, that discrepancies between satisfaction and usage must be attributable to biasing contextual factors. It is not enough in any one case to show that there is a poor relationship between satisfaction and behaviour; all one needs for that are measuring instruments of poor discriminability. If a poor relationship is found, then one must hunt to find the biasing contextual factors.

**CONCLUSION**

The preceding discussion illustrates that Melone (1990) was correct in asserting that a broad conceptualisation of satisfaction as an attitude retains the construct’s “essential elements” while enabling
access to the necessary theoretical foundation for research in this area. The discussion has gone on to attempt to uncover what these essential elements are. It was argued that using theories and models from the attitude literature can help with some of the challenges faced by researchers, particularly in constructing definitions and operationalisations of satisfaction which may lead to scales of measurement.

The gist of this paper can be summarised in four statements.

First, it is proposed here that the construct should not be broadened as this changes the construct into unrecognisable forms. It will lead to greatest consensus to define satisfaction (based on Ajzen’s 2001 definition of attitude) as a summary evaluation of an interactive system captured in terms of how easy a user thinks a system is to use. For HCI, satisfaction as so defined is an element of the construct of Usability. Defining it in this manner ensures that satisfaction remains a measure of usability as *quality in use*, rather than a broader measure of the entire user experience.

Second, it is suggested that research into the structure of the satisfaction concept is important. This kind of research seeks to discover the main directions along which users are thinking when they interact with a particular class of products. It is likely that such thinking will change over time as technology is assimilated into the way we live. Structural information can be used formatively (in the development of technology), as well as summatively (in the assessment of technology.)

Third, it is proposed that satisfaction is the result of an evaluative state in the user that can be formed through affective, cognitive, or behavioural processes. These processes may be related through emotion, but satisfaction is not an exclusively emotional response on the part of the user toward a product.

Finally, it is suggested that in accordance with the conceptualisation of usability as *quality of use*, the level of user satisfaction with a product is dependent on the interaction between a user and a product, and the context in which that interaction takes place. Satisfaction should not be regarded as being solely a product attribute.

We propose that these are four fundamental principles in the development of scales of measurement of the concept of user satisfaction in HCI.

ABSTRACT
The chapter introduces the concept of user-centric evolutionary design and decision-support systems, and positions them in terms of interactive evolutionary computing. Current research results provide two examples that illustrate differing degrees of user interaction in terms of subjective criteria evaluation; the extraction, processing, and presentation of high-quality information; and the associated improvement of machine-based problem representation. The first example relates to the inclusion of subjective aesthetic criteria to complement quantitative evaluation in the conceptual design of bridge structures. The second relates to the succinct graphical presentation of complex relationships between variable and objective space, and the manner in which this can support a better understanding of a problem domain. This improved understanding can contribute to the iterative improvement of initial machine-based representations. Both examples complement and add to earlier research relating to interactive evolutionary design systems.

INTRODUCTION
Uncertainty and poor problem definition are inherent features during the early stages of design and decision-making processes. Immediate requirements for relevant information to improve
understanding can be confounded by complex design representations comprising many interacting variable parameters. Design constraints and multiple objectives that defy complete quantitative representation and therefore require a degree of subjective user evaluation further inhibit meaningful progression. Machine-based problem representation may, initially, be based upon qualitative mental models arising from experiential knowledge, group discussion, and sparse available data. However, such representations, coupled with user intuition, play a significant role in defining initial direction for further investigation. Concepts based upon current understanding require both quantitative and qualitative exploration to generate relevant information that supports and enables meaningful progress.

The chapter presents research and development relating to powerful machine-based search and exploration systems that, through appropriate user interaction, allow both quantitative and qualitative evaluation of solutions and the extraction of information from complex, poorly understood design and decision-making domains. The integration and capture of user experiential knowledge within such systems in order to stimulate, support, and increase understanding is of particular interest. The objective is the realisation of user-centric intelligent systems that overcome initial lack of understanding and associated uncertainty, support an improving knowledge-base, allow the integration of subjective judgement, and stimulate innovation and creativity.

**INTERACTIVE EVOLUTIONARY COMPUTATION (IEC)**

Interactive evolutionary computing (Takagi, 1996) mainly relates to partial or complete human evaluation of the fitness of solutions generated from evolutionary search. This has been introduced where quantitative evaluation is difficult if not impossible to achieve. Examples of application include graphic arts and animation (Sims, 1991), food engineering (Herdy, 1997), and hazard icon design (Carnahan, 2004). Such applications rely upon a human-centred, subjective evaluation of the fitness of a particular design, image, taste, and so forth, as opposed to an evaluation developed from some analytic model.

Partial human interaction that complements quantitative machine-based solution evaluation is also evident—for instance, the user addition of new constraints in order to generate solutions that are fully satisfactory within an evolutionary nurse scheduling system (Inoue, Furuhashi, & Fujii, 1999). Another example is the introduction of new compounds as elite solutions into selected evolving generations of a biomolecular design process (Levine, Facello, & Hallstrom, 1997).

These examples utilise a major advantage of stochastic population-based search techniques—that is, their capabilities as powerful search and exploration algorithms that provide diverse, interesting, and potentially competitive solutions to a wide range of problems. Such solutions can provide information to the user which supports a better understanding of the problem domain whilst helping to identify best direction for future investigation (Parmee & Bonham, 1999), especially when operating within poorly defined decision-making environments. Extracted information supports development of the problem representation in an iterative, interactive evolutionary environment. Interactive evolutionary design systems (IEDSs) represent a human-centric approach (Parmee, 2002; Parmee, Watson, Cvetkovic, & Bonham, 2000) that generate and succinctly present information appertaining to complex relationships between the variables, objectives, and constraints that define a developing decision space.

In an attempt to categorise these various forms of IEC, it is possible to view complete human evaluation as explicit, whereas partial evaluation and interaction are less explicit, more subtle forms of human involvement. Completely implicit interaction occurs where users are unaware of their role.
in the evolution of a system (e.g., the Web-based tutorials of Semet, Lutton, Biojout, Jamont, & Collet, 2003). A simple implicit/explicit spectrum of interactive evolutionary approaches can thus be developed (Parmee & Abraham, 2005).

The following sections concentrate on the manner in which evolutionary search and exploration can generate high-quality information from complex design and decision-making environments. Such information can be utilised interactively to:

- support the identification of high-performance solutions where qualitative as well as quantitative objectives play a major role; and
- modify and refine design problem representation.

The first example relates to aesthetic judgement of EC-generated designs and is closer to the more traditional explicit interaction where user subjective evaluation is evident. However, this subjective evaluation complements detailed, machine-based quantitative evaluation. The second is current IEDS research relating to problem definition and the iterative interactive improvement of machine-based design representations that sits further toward the implicit end of the spectrum.

INTEGRATING AESTHETICS VIA INTERACTIVE EVOLUTIONARY DESIGN PROCESSES

This example brings together agent-based machine learning, evolutionary computing, and subjective evaluation in search for aesthetically pleasing, structurally feasible designs during the conceptual design process. Although significant theoretical work is evident with respect to the inclusion of aesthetics in computer-based design, application-based research has received less attention (Moore, Miles, & Evans, 1996a, 1996b; Saunders, 2001).

Figure 1 illustrates the main components of the system and the manner in which they interact. The user defines initial design requirements and aesthetically evaluates the designs generated by the Evolutionary Search, Exploration, and Optimisation System (ESEO) during the initial generations. The agents have multiple tasks, which include the creation of the initial population based on design requirements, the monitoring of designs for feasibility during the ESEO processes, and evaluation of machine-based aesthetic criteria. The ESEO identifies design solutions that can be considered high performance in terms of Structural Feasibility and Stability, Materials Cost, and Rule-Based Aesthetics.

*Figure 1. The user-centric system*
The project is initially considering three test domains: bridges; liquid containers such as wine glasses, chemical tanks, and so forth; and street furniture in the form of bench type structures. The following example concentrates on bridge design. Research involves the ACDDM Lab at Bristol UWE and the Institute of Machines and Structures at Cardiff University. The early stages have concentrated on development of highly flexible and robust representations of simple bridge structures and the identification of optimal solutions via basic evolutionary algorithms.

**Representation**

Problem representation affects search efficiency and evolutionary performance (Rosenman, 1997; Goldberg, 1989). Genetic algorithms (GAs), evolutionary strategies (ESs), and evolutionary programming (EP) representations are generally based on binary or real number parameter strings, but many alternatives are also available. Component-based and hierarchical representations support flexibility and robustness in terms of accommodating complex design entities with many related sub-systems/components (e.g., Bentley, 2000; Cramer, 1985; Rosenman, 1996).

It is also necessary to consider which stochastic search process would best suit a chosen representation in terms of efficient negotiation of the design space. As a high degree of solution search and exploration is required, a population-based approach would seem most appropriate. GAs, EPs, and ESs offer high utility with differing operators. GAs use crossover as the main operator (Goldberg, 1989). ESs are similar to real parameter GAs without crossover, although crossover-like operators have been introduced (Deb, 2001). EPs (Fogel, 1988) is a purely mutation-based evolutionary algorithm and therefore perhaps represents the simplest of the three, as the selected representation does not need to support crossover between differing variable strings. GAs, however, require a representation that is robust enough to handle repeated crossovers whilst ensuring offspring feasibility. ESs could be considered to lie somewhere between these two. EPs have been selected in this work primarily to overcome feasibility maintenance problems relating to the component-based representation and crossover.

The initial goal was a flexible enough representation to model all possible designs which is robust enough to be manipulated by design search and exploration processes (Machwe, Parmee, & Miles, 2005). A collection-based object-oriented representation has been developed. A single population member (chromosome) is a collection of primitive elements that represent a design. Different elements with different design properties can be included in the set of possible design primitives. The evaluation of fitness of the structure and checking the structural integrity utilises secondary properties of the particular primitive element type. Figure 2 further clarifies the idea of using an object-based representation. A simple bridge design is basically divided into

---

**Figure 2. Details of the object-based representation**
two separate collections. These are the *span element* collection containing elements which form the span of the bridge and the *support element* collection containing elements which form the support of the bridge. In the case of a simple, end-supported span, the support element collection will be empty.

The rectangular elements can either be part of a supporting element collection or a span element collection. Simple beam or angled beam span bridges with and without support require only two basic types of elements—the angled section element (to be used as a span element only) and a simple rectangle element, which can be used as both a spanning and supporting element. All elements have an assumed constant. The object-based representation can take advantage of the principles of object-oriented programming such as inheritance—that is, if we want to add a new kind of element, say curved span section, we could easily do so by extending the basic properties of element and adding the extra properties required for a curved section.

During initial design activity, it may not be desirable or possible to strictly parameterise a design. Designs make the transition from abstract concepts to well-defined specifications. The above object-based representation can represent designs at all levels, including at the abstract level by using high-level objects/elements and at the well-defined level as a set of specifications. Functionality can be modified based upon changing requirements. Thus objects offer a straightforward way to cover design activity at all levels. To produce the same in a simple string-based chromosome would require additional checks to ensure consistency of the chromosome is not violated once a bit or real number is added or removed, or its functionality modified. The overall system would be overly complex and difficult to manipulate.

**Mutation**

Let us assume the chromosome to be mutated represents the design in Figure 3.

This is a basic beam bridge simply supported at either end with a single intermediate support (B3) and two span elements (B1, B2). L is the span and H is the maximum height of the bridge (see Figure 4).

The mutation is rule based, and a rule is selected randomly. There are separate rules for the two arrays of elements. The supports can only move left or right. Their height is based upon the
thickness of the spanning element they support. Hence there are only four rules for supports: two rules for left and right movement, and two for increasing and decreasing width. The depth of each span element can vary, but they must have a level upper surface and must be continuous with no overlap or space between them. Thus for a simple element in a span, there are just two rules, namely to increase or decrease the span depth. Now, for example, if the selected rule for support (B3) is to move it left by a constant distance (say two units) and for span to decrease thickness of B2 support by constant units (say two units again), then the B3 object in the support array will have its X value attribute decreased by two units and the B2 object in the span array will have its height value attribute decreased by two units. The height attribute of the support will be automatically adjusted to make it continuous and remove any overlap at its new position. The mutated design is shown in Figure 5.

**Introduction of Agency**

Initial testing of the representation involved freeform assembly and evolution of simple bridge structures using GA, EP, and agent-based approaches. Evolving feasible structures proved a difficult and lengthy process, whereas rule-based agent assembly was straightforward and rapid. Thus a combined approach has been developed where agents create the initial population of structures and provide a continuous ‘repair’ capability, and an evolutionary system performs search, exploration, and optimisation across the space of possible structures.

The construction and repair agents (CARAs) have the task of assembling structures with varying size and shape regarding span and supports. Agents are given specifications relating to restrictions on placement of supports and types of span section. Thus CARAs are informed of the design environment and will create initial population designs within it. The evolutionary process then takes care of the SEO process, with the CARAs keeping a check on potentially disruptive processes and repairing the structure, where necessary, to ensure feasibility.

**Simple Structural Criteria**

The CARAs can currently create three kinds of bridges:

- simple beam bridges without supports (Type 1a);
- simple beam bridges with supports (Type 1b); and
- simple beam bridges with sloping span sections and supports (Type 2).

An initial population can consist of a mixture of these designs which are then evaluated against structural and aesthetic criteria. In terms of structure, solutions are assessed via simple length/depth ratios and minimising material. Column design is subjected to buckling criteria.
Fitness Evaluation for Type 1A

Type 1A is treated as a simple beam deflection problem under uniform distributed loading. A simple heuristic relating to an ideal length-to-height ratio for a span element of 20:1 is utilised—that is, the closer a span section is to the ideal ratio \( R \), the better its fitness.

\[ F_i = R - \left( \frac{L_i}{H_i} \right) \]  
\[ \text{Stability} = \frac{1}{(1 + \sum f_i)} \] (1)

To ensure the overall integrity of the structure, the above equations are used. It is evident that the closer the dimensions of the span elements are to the ideal ratio \( R \), the lower the value of \( F_i \) will be. At the minimum, all \( F_i \)'s are equal to zero and thus stability is equal to one.

Fitness Evaluation for Type 1b and Type 2

In Type 1b the buckling in the columns due to the weight of the loaded beam is also considered using:

\[ P' = \frac{\pi^2 EI}{H^2} \] (3)

where: \( P' \) = maximum possible load, \( E \) = modulus of elasticity, \( I \) = moment of inertia, and \( H \) = column height. The load on column is determined from the length of the beam between the end supports, calculating the loading and distributing this loading across intermediate supports. A column satisfying the buckling criteria can either increase or decrease in thickness. Otherwise it can only increase in thickness.

Example

A basic EP approach is used with a population size of 100 solutions. Tournament selection is utilised with a tournament size of 10, and the system is run for 100 generations. A few members from the initial population are shown in Figure 6.

The initial population consists of three different kinds of designs: a simply supported span, a span with columns, and an angled span bridge. After 100 generations the optimal designs shown in Figure 7 are achieved. The angled span bridges turn out to be most efficient in terms of structural criteria (i.e., stability and material usage). The
other two design types have been evolved out of the population.

Aesthetics and User Evaluation

It is very difficult to integrate subjective aesthetic criteria with machine-based design unless user interaction plays a significant role. Moore et al. (1996a, 1996b) have published significant work in this area which has contributed to a New South Wales RTA set of guidelines on bridge aesthetics (Road and Traffic Authority, 2004). However, aesthetics evaluation can only be partially quantified by generic guidelines and rules. While aesthetically pleasing shapes can be explicitly specified to some extent, complete aesthetic evaluation must also involve the designer—that is, evaluation must involve both rule-based and subjective factors. In the present system the following aesthetics have been hard coded:

- symmetry of support placement (A1),
- slenderness ratio (A2),
- uniformity in thickness of supports (A3), and
- uniformity in thickness of span sections (A4).

Many other such rules are currently being evaluated and included in the work as the design representation is developed to support detailed aesthetic evaluation. Each aesthetic rule is evaluated by a separate aesthetic agent. The rule-based aesthetic fitness is calculated as:

\[ \text{Aesthetic Fitness} = \sum_{i=1}^{4} w_i A_i \]  

(4)

where \( w_i \) are weights for each of the aesthetic rules (\( A_i = \text{A1 to A4} \)) which can also be modified online.

In addition, user-assigned aesthetic fitness (Ufit) is the fitness given to a design directly by the user on a scale of 0 to 10 (10 being the best). The user can also mark solutions for preservation into the next generation. Overall user evaluation operates thus:

1. User stipulates the frequency of user interaction (e.g., once every 10 generations).
2. User aesthetically evaluates a preset number of population members from the initial population (usually the top 10 members, i.e., those with highest fitness regarding stability, material usage, and explicitly defined aesthetic criteria).
3. The EP system runs.
4. Population members are aesthetically evaluated by the user every \( n \) generations.
5. Repeat steps 3 and 4 until user terminates the evolutionary process.

The overall fitness function now includes aesthetic fitness and user-assigned aesthetic fitness. Furthermore, weights have been added (w1 to w4) to each of the objectives which the user can modify online to influence evolutionary direction (See Box 1).

Figure 8 shows aesthetically pleasing cross-sections after 30 generations with user evaluation every 10 generations. The aesthetic objectives (A1 to A4) are clearly reflected in them. The span elements are of the same size. The supports are of nearly uniform thickness, and their placement is also symmetric.

Box 1.

\[ \text{Fitness} = (w1 \times \text{Stability}) + (\frac{w2}{\text{Material Usage}}) + (w3 \times \text{Aesthetic Fitness}) + (w4 \times \text{Ufit}) \]  

(5)
Figure 8. Aesthetically pleasing cross-sections

![Cross-sections](image)

Furthermore, due to user interaction, the optimised shapes are not limited to angled sections but take on a variety of different aesthetically pleasing shapes that not only satisfy the explicitly defined aesthetic guidelines (A1 to A4) but also the implicit aesthetics of the user (Ufit).

### Incorporating Learning

Current work involves the introduction of supervised learning taking user evaluation into account. Since there is a natural classification in the designs (i.e., angled spans, supported beams, and unsupported beams), learning is attempted at two levels. The first level determines user preference for one of the three types of bridge design. This is achieved by evaluating the relative difference between user-assigned fitness (or rank) for each type of design. The second level assesses what kind of features the user finds pleasing in the different designs. Figures 7 and 8 indicate that for the angled spans, there are two features that catch the eye immediately. These are the peak of the bridge (that is the location of the rise point) and the thickness of the span sections. Such features are converted into fuzzy variables to create an aesthetic model of the particular bridge type. For the angled section the following fuzzy variables are used to specify the aesthetic model:

1. **Peak**: Left, Central, Right
2. **Difference in Span Thickness**: Left Thicker, Equal Thickness, Right Thicker
3. **Average Thickness**: Low, Medium, High
4. **Column Thickness**: Low, Medium, High
5. **User-Assigned Fitness (Ufit)**: Low, Medium, High

Similar models can be created for supported beam spans and unsupported beam spans. Based on this model a fuzzy rule generator has been implemented. Initial results have been encouraging. The intention is that as search progresses there will be a gradual lessening of the degree of user interaction allied with an increasing degree of autonomous machine-based solution evaluation involving both aesthetic and structural criteria. This addresses the problem of user fatigue.

### EVOLVING THE PROBLEM SPACE THROUGH INTERACTIVE EVOLUTIONARY PROCESSES

The second illustration of the utilisation of user-centric evolutionary computing relates to a more implicit form of interaction. This is aimed primarily at the extraction of high-quality information and the succinct presentation of such information to the designer/decision maker in such a manner that supports a better understanding of complex relationships between variables, multiple objectives, and constraints during conceptual design. This complements the initial IED concept by further attempting to meld experiential knowledge and intuition with powerful machine-based search, exploration, and information processing.

Machine-based problem representations support exploration through the evaluation of solutions against seemingly relevant criteria. Although initial representations may be relatively basic, and confidence in model output will be low, such representations can provide essential problem insight despite apparent shortfalls. Identified high-performance solutions based upon quantitative criteria followed by qualitative human evaluation may provide an indication of concept viability and model fidelity. An iterative user/machine-based process can commence where gradual improvements in understanding contribute to the development of better representations, a growing knowledge base, and the establishment of computational models that support
rigorous analysis—that is, a process emerges that supports the development of representation through knowledge discovery.

An initial variable parameter set may be selected with later addition or removal of variables as the sensitivity of the problem to various aspects becomes apparent. Constraints may be treated in the same way with the added option of softening them to allow exploration of non-feasible regions. Included objectives may change as significant payback becomes apparent through a reordering of objective preferences. Some non-conflicting objectives may merge, whilst difficulties relating to others may require serious re-thinking with regard to problem formulation. The initial design space is therefore a moving feast rich in information (Parmee, 2002).

The visualisation of variable and objective space from cluster-oriented genetic algorithm (COGA) output provides a variety of perspectives illustrating complex relationships (Parmee & Abraham, 2004). This information is further defined by data mining, processing, and visualisation techniques. The intention is to support implicit learning and reduce complexity by supporting the designer development of a quantitative and intuitional understanding of the problem. This leads to the iterative model development described above.

COGAs and the MiniCAPs Model

Cluster-oriented genetic algorithms provide a means to identify high-performance (HP) regions of complex conceptual design spaces and enable the extraction of information from such regions (Parmee, 1996). COGAs identify HP regions through the online adaptive filtering of solutions generated by a genetic algorithm. COGA can be utilised to generate design information relating to single and multi-objective domains (Parmee & Bonham, 1999). The technique has been well documented (see http://www.ad-comtech.co.uk/Parmee-Publications.htm for relevant papers).

The research utilises the BAE Systems’ MiniCAPs model, a simplified version of a suite of preliminary design models for the early stages of military aircraft airframe design and initially developed for research relating to the development of the IED concept. The model comprises nine continuous input variables and 12 continuous output parameters relating to criteria such as performance, wing geometry, propulsion, fuel capacity, structural integrity, and so forth. Input variables are:

1. Climb Mach Number (CLMN)
2. Cruise Height (CH)
3. Cruise Mach Number (CRMN)
4. Gross Wing Plan Area (GWP)
5. Wing Aspect Ratio (WAR)
6. Wing Taper Ratio (WTR)
7. Wing Lead Edge Sweep (WLES)
8. Wing T/C Ratio (WTCR)
9. By Pass Ratio (BPR)

Identifying High-Performance Regions Relating to Differing Objectives

Figures 9(a), (b), and (c) show HP regions comprising COGA-generated solutions relating to three of the 12 MiniCAPS objectives (Ferry Range—FR, Attained Turn Rate—ATR1, and Specific Excess Power—SEP1) projected onto a variable hyperplane relating to two of the nine variables utilised in the search process. This projection allows the designer to visualise the HP regions, identify their bounds, and subsequently reduce the variable ranges as described in previously referenced papers. These papers also introduce the projection of these differing objective HP regions onto the same variable hyperplane as shown in Figure 10 from which the degree of objective conflict immediately becomes apparent to the designer. The emergence of a mutually inclusive region of HP solutions relating to the ATR1 and FR objectives indicates...
Figure 9. COGA-generated high-performance regions relating to three differing objectives: (a) FR—Ferry Range; (b) ATR1—Attained Turn Rate; (c) SEP1—Specific Excess Power. All projected onto the GWPA (Gross Wing Plan Area)/WAR (Wing Aspect Ratio) variable hyperplane (N.B. Colour versions of figures can be found at: http://www.ad-comtech.co.uk/cogaplots.htm)

![Graph](image)

(a) 

(b) 

(c)

a low degree of conflict, whereas the HP region relating to SEP1 is remote (in variable space) to both the ATR1 and FR regions, indicating a higher degree of conflict.

There is much information contained in the HP regions relating to appropriate variable ranges for single objectives, degree of conflict between multiple objectives, and the emergence and definition of mutually inclusive (common) HP regions. This graphical representation provides an excellent spatial indication of the degree of objective conflict. However, searching through all possible two-dimensional variable hyperplanes to visualise such information is not a feasible approach. Recent research has resulted in single graphical representations that can present all variable and objective data whilst providing links to other visual perspectives. The parallel coordinate box plot (PCBP) representation shown in Figure 11 is one such graphic that provides a central repository containing much single and multiple-objective solution information.
Parallel Coordinate Box Plots

Parallel coordinate plots (Inselberg, 1985) appeared to offer potential in terms of providing a single graphic illustrating complex relationships between variable and objective space. Parallel coordinate representation displays each variable dimension vertically parallel to each other. Points corresponding to a solution's value of that variable can then be plotted on each vertical variable axis. It is thus possible to show the distribution of solutions in all variable dimensions and the correlation between different dimensions. The disadvantage of the technique when attempting to include multiple objectives is that the density of the information presented hinders perception (Parmee & Abraham, 2004, 2005). To overcome the ‘data density’ problem, three modifications to the standard parallel coordinate representation have been included:

1. additional vertical axes for each variable so that each objective can be represented,
2. an indication of the degree of HP region solution cover across each variable range, and
3. the introduction of box plots to indicate skewness of solutions across each variable range.

This PCBP provides a much clearer graphic (see Figure 11). The vertical axis of each variable is scaled between the minimum and maximum value of the variable in the HP region solutions of each objective. The length of the axis represents the normalised ranges of variable values present in an HP region. Where an HP solution set does not fully extend across the variable range, the axis is terminated by a whisker at the maximum or minimum value of the variable. The colour-coded box plots relate to each objective (i.e., SEP1, ATR1, and FR). The median is marked within the box, and the box extends between the lower and upper quartile values within the variable set. The PCBP clearly visualises the skewness of solution distribution relating to each objective in each variable dimension which provides an indication of the degree of conflict between objectives.

For instance, it is apparent that all three objective boxes overlap in the case of variables 1, 2, 3, 6, and 9. However, significant differences in the distribution of the boxes are evident in terms of at least one objective where variables 4, 5, 7, and 8 are concerned. Variables 4 and 5 are Gross Wing Plan Area and Wing Aspect Ratio. The conflict between SEP1 and FR/ATR1 evident in Figure 10 is strongly reflected in the HP solution distribution indicated by the whisker truncation of variable 4 in Figure 11 and in the box plots of that variable. In terms of variable 5, the whisker terminations relating to ATR1 and FR in Figure 11 reflect the extent of the solution distribution across their HP regions in Figure 10. The box plots also reflect the relative distribution of HP solutions of all objectives along that variable plane as illustrated in Figure 10. Figure 12 shows a projection of the ATR1 HP region onto the Cruise Height (variable 1) and Climb Mach No (variable 2) hyperplane. The relatively uniform distribution of HP solutions across the hyperplane is reflected in the appropriate variable plots of Figure 11.

The PCBP represents a single graphic from which the designer can perceive which variables are causing high degrees of objective conflict. To get an alternative, very clear perspective of these conflicts, any two of these variables can be selected to also view the relevant graphics similar to Figure 10. Further reinforcement can be obtained from the perspectives explored in the following section relating to projections upon objective space. Improved understanding can lead to developments of the computational representation and to appropriate setting of objective preferences.
Projection of COGA Output on to Objective Space

The HP region solutions for ATR1 and FR can be projected onto objective space as shown in Figure 13. A relationship between the HP region solutions and a Pareto-frontier emerges along the outer edge of the plot (Parmee & Abraham, 2004) despite the fact that the working principle of COGA is very different to that of evolutionary multi-objective algorithms (Deb, 2001), which tend to use a non-dominance approach.

For comparative purposes, Figure 14 illustrates the distribution of COGA output and SPEA-II (Zitzler et al., 2002) Pareto-front output in objective space. Using a standard multi-objective GA (MOGA), it is possible to obtain solutions lying along the Pareto-front, but difficult to explore the relationship between variable and the objective space. However, it is likely that the designer is also interested in solutions that lie around particular sections of the Pareto-front.
The COGA approach therefore provides a good visual indication of the degree of conflict between objectives, an opportunity to explore varying objective preferences and view their effect upon HP region bounds, and the ability to generate an approximate Pareto-front relating to the objectives under investigation plus solutions around the Pareto-front. This is in addition to the utility of COGA in single-objective space as described in previous referenced papers. All of this utility directly complements the original IEDS concept regarding information extraction, processing, and presentation.

SUMMARY AND CONCLUSION

The aesthetics work reveals a significant potential in terms of the development of systems that include criteria ranging from purely quantitative through to purely subjective. Ultimately the system will be required to give a comparative indication in terms of aesthetically pleasing design and likely cost whilst indicating structural feasibility.

The introduction of such an interactive process also poses many questions such as:

- How many designs from each population should be presented to the user?
- How should these be selected?
- How many evaluations can a user be expected to perform before becoming fatigued?

These questions have been repeatedly posed, but seldom successfully addressed within the interactive evolutionary computing (IEC) community. Our continuing research is addressing these issues and, in particular, the user-fatigue aspect.

The integration of user preference and user-varied objective weights supports the transfer of subjective evaluation from the user to a design/decision-making system. In order to address the third question above, a machine learning system is required which learns the preferences of the user during the interactive process. User fatigue is perhaps the major stumbling block in the development of successful systems. Much work is required to develop an appropriate, fully functioning, machine-learning sub-system. The fuzzy rule-based learning system is not ideal, and current work is investigating a case-based approach.

The developing system should be seen as a generic framework for the integration of user-evaluation with any preliminary design/decision-making domain. The CARA-EP representation concept should be portable across many problem domains. Any system must significantly decrease the load on the user as early as possible in the evolutionary process. A multi-agent-based learning environment is therefore under investigation that gradually replaces the subjective criteria evaluation.

It is apparent from previous research and the research presented here that COGA-generated data can provide visual representations in variable space of the degree of conflict between objectives and excellent spatial indications of the distribution of high-performance solution regions relating to
a number of objectives. It is also apparent that the COGA HP solution sets, when projected onto objective space, provide the designer with an opportunity to explore a wealth of HP solutions that offer varying degrees of objective compromise and a variety of design characteristics. The non-dominance sorting of these solutions also provides an approximate Pareto-frontier illustrating succinct available trade-offs. The direct mapping of solutions between objective and variable space facilitates an understanding of the relative utility of solutions in terms of preferred variable ranges and particular design characteristics.

The PCBP of Figure 11 offers a first point of call for the designer to get an overview of the varied information available from COGA output. The intention is that the COGA graphical perspectives will be available through simple menu/clicking operations from the central PCBP image. These differing perspectives are seen as essential aids to understanding overall complexities relating to the two dependant design spaces (variable vs. objective space).

There is a wealth of information available from COGA output relating to single objective solutions that is also inherent within the multi-objective output. Hence the utility of the approach should be assessed across both areas. The information available from single-objective HP regions has been fully discussed in previous referenced papers.

User-centric techniques described in the chapter and variations of them are also currently being applied in the conceptual design of submersible vehicles (Parmee & Abraham, 2005), pharmaceutical drug design and discovery (Sharma & Parmee, 2005), and conceptual software design (Simons & Parmee, 2004). Details of this associated work can be found on the ACDDM Web site at www.ad-comtech.co.uk/ACDDM_Group.htm.

ACKNOWLEDGMENT

The authors wish to acknowledge the contribution to the bridge aesthetics work of Professor John Miles of the Institute of Machines and Structures at the University of Cardiff.

Chapter 2.3
Adaptation and Personalization of User Interface and Content

Christos K. Georgiadis
University of Macedonia, Thessaloniki, Greece

ABSTRACT

Adaptive services based on context-awareness are considered to be a precious benefit of mobile applications. Effective adaptations however, have to be based on critical context criteria. For example, presence and availability mechanisms enable the system to decide when the user is in a certain locale and whether the user is available to engage in certain actions. What is even more challenging is a personalization of the user interface to the interests and preferences of the individual user and the characteristics of the used end device. Multimedia personalization is concerned with the building of an adaptive multimedia system that can customize the representation of multimedia content to the needs of a user. Mobile multimedia personalization especially, is related with the particular features of mobile devices’ usage. In order to fully support customization processes, a personalization perspective is essential to classify the multimedia interface elements and to analyze their influence on the effectiveness of mobile applications.

INTRODUCTION

Limited resources of mobile computing infrastructure (cellular networks and end user devices) set strict requirements to the transmission and presentation of multimedia. These constraints elevate the importance of additional mechanisms, capable of handling economically and efficiently the multimedia content. Flexible techniques are needed to model multimedia data adaptively for multiple heterogeneous networks and devices with varying capabilities. “Context” conditions (the implicit information about the environment, situation and surrounding of a particular communication) are of great importance.

Adaptive services based on context-awareness are indeed a precious benefit of mobile applications: in order to improve their provided service, mobile applications can actually take advantage of the context to adjust their behaviors. An effective adaptation has to be based on certain context criteria: presence and availability mechanisms enable the system to decide when the user is in a certain locale and whether the user is available
to engage in certain actions. Hence, mobile applications aim to adapt the multimedia content to the different end user devices.

However, typically each and every person receives the same information under the same context conditions. What is even more challenging is a personalization of the user interface (UI) to the interests and preferences of the individual user and the characteristics of the user end device. The goal of mobile applications is to increasingly make their service offerings more personalized toward their users. Personalization has the ability to adapt (customize) resources (products, information, or services) to better fit the needs of each user. Personalization in mobile applications enables advanced customized services such as alerts, targeted advertising, games, and improved, push-based mobile messaging. In particular, multimedia personalization is concerned with the building of an adaptive multimedia system that can customize the representation of multimedia content to the needs of a user.

Multimedia personalization enlarges the application’s complexity since every individual’s options have to be considered and implemented. It results in a massive amount of variant possibilities: target groups, output formats, mobile end devices, languages, locations, etc. Thus, manual selection and composition of multimedia content is not practical. A “personalization engine” is needed to dynamically create the context-dependent personalized multimedia content. General solution approaches concerning the personalization engine, include personalization by transformation (using XML-based transformations to produce personalized multimedia documents), adaptive multimedia documents (using SMIL-like presentation defined alternatives), personalization by constraints (optimization problem—constraint solving), personalization by algebraic operators (algebra to select media elements and merge them into a coherent multimedia presentation), or broader software engineering approaches.

Mobile multimedia (M3) personalization especially, is related with the particular features of mobile devices’ usage. Because of their mobility and omnipresence, mobile devices have two characteristics worth noticing. First, users have limited attention as they operate their mobile devices (this is because they usually are concerned at the same time in other tasks, e.g., car driving). Second, users tend to treat their mobile devices in a quite personal way, seeking for personal services and personalized content. The preferences of users are therefore noticeably affected. In many cases, they favor content and services which do not require transmitting large quantities of information. Thus, low-intensity content (e.g., ring tones, weather reports, and screen icons) proved to be very popular. This is not only because of the low availability of mobile devices’ resources which complicates the processing of large volumes of information. Users demand further individually customized content on the mobile Internet because its personalization level is higher than that of the fixed Internet.

Detailed issues concerning M3 personalization can be described, analyzing UI design issues. Existing mobile applications offer a reasonably easy, browser-based interface to help user access available information or services. In order to support adaptation and personalization mechanisms they should be also as far as possible concentrated on the individual prerequisites of the human in contact with it. In this chapter, after the presentation of background topics we discuss critical issues of the mobile setting (characteristics of mobile applications and mobility dimensions in user interactions) that influence adaptation and personalization technologies. Then, as an application case, we focus on m-commerce applications and customer interfaces. All current research studies tend to acknowledge that the design rules of wired Internet applications are only partially useful. They should not be directly adopted in mobile computing area, because of the considerably different user requirements and device constraints. On the other hand, experi-
Adaptation and Personalization of User Interface and Content

ence gained from the fixed Internet formulated as the well-accepted 7C framework, is always welcomed. Hence, we classify the multimedia interface elements and we analyze their influence on m-commerce site’s effectiveness from a personalization perspective.

BACKGROUND

Adaptation Objectives

The diversity of end device and network capabilities in mobile applications along with the known multimedia challenges (namely, the efficient management of size, time, and semantics parameters of multimedia), demand media content and service to be flexible modeled for providing easy-to-use and fast multimedia information. Multimedia adaptation is being researched to merge the creation of the services so that only one service is needed to cover the heterogeneous environments (Forstadius, Ala-Kurikka, Koivisto, & Sauvola, 2001). Even though adaptation effects could be realized in a variety of ways, the major multimedia adaptation technologies are adaptive content selection, and adaptive presentation. Examples of adaptation include “down-scaling” the multimedia objects and changing the style of multimedia presentation according to user’s context conditions.

In general, adaptive hypermedia and adaptive Web systems belong to the class of user-adaptive systems. A user model—the explicit representation of all relevant aspects of a user’s preferences, intentions, etc.—forms the foundation of all adaptive systems (Bauer, 2004). The user model is used to provide an adaptation effect, which is tailoring interaction to different users. The first two generations (pre-Web and Web) of adaptive systems explored mainly adaptive content selection and adaptive recommendation based on modeling user interests. Nowadays, the third (mobile) generation extends the basis of the adaptation by adding models of context (location, time, bandwidth, computing platform, etc.) to the classic user models and explores the use of known adaptation technologies to adapt to both an individual user and the context of the user’s work (Brusilovsky & Maybury, 2002).

Personalization Objectives and Mechanisms

Personalization is a special kind of adaptation of the UI which focuses on making a Web application more receptive to the unique and individual needs of each user (Cingil, Dogac, & Azgin, 2000). Personalization mechanisms presuppose two phases. First, the accumulation of user information, in order to build up a profile that illustrates a set of descriptors essential to administrators (e.g., visitor’s interest, navigation paths, entitlements and roles in an organization, purchases, etc.). The second phase is the analysis of user information to recommend actions specific to the user.

To develop the best recommendation, rule-based practices (allowing administrators to specify principles for their applications to thrust personalization) are usually combined with filtering algorithms which analyze user profiles (Pierakos, Paliouras, Papatheodorou, & Spyropoulos, 2003). Simple filtering techniques are based on predefined groups of users, classifying their accounts by age groups, asset value etc. Content-based filtering can be seen as locating objects comparable to those a user was fond of in the past. Finally, collaborative filtering builds up recommendations by discovering users with similar preferences.

CONTENT ADAPTATION AND PERSONALIZED USER INTERFACE

Analyzing Mobile Setting

The characteristics of the mobile Internet applications can be appreciated from three different
Adaptation and Personalization of User Interface and Content

viewpoints: system, environment, and user (Chae & Kim, 2003). From the system’s viewpoint, mobile applications present disadvantages, because they provide a lower level of available system resources. Mobile devices, especially cellular phones, have lower multimedia processing capabilities, inconvenient input/output facilities (smaller screens/keyboards), and lower network connection speeds than desktop computers. However, from the environmental viewpoint there is an uncontested benefit: they enable users to access mobile Internet content anywhere and anytime. The term “instant connectivity” is used for mobile browsing to describe actually the fact that it is possible to do it at the moment of need.

User’s perspective characteristics must be regarded rather differently, because they are to a certain degree consequences of the system and of the environment. In addition, the multi-dimensional concept of “mobility” influences on them in many ways. Mobile users perform their tasks in terms of place, time and context. Different terms are used by the research community to describe user’s mobile setting, and their interactions within it, but these converge at the ones described below (Kakihara & Sorensen, 2001; Lee & Benbasat, 2004):

Figure 1. Analyzing mobile setting
Spatial mobility denotes mainly the most immediate dimension of mobility, the extensive geographical movement of users. As users carry their mobile devices anywhere they go, spatiality includes the mobility of both the user and the device.

Temporal mobility refers to the ability of users for mobile browsing while engaged in a peripheral task.

Contextual mobility signifies the character of the dynamic conditions in which users employ mobile devices. Users’ actions are intrinsically situated in a particular context that frames and it is framed by the performance of their actions recursively.

Because of their mobility (and in correspondence with its dimensions), we distinguish three attributes regarding mobile device usage:

1. Users have a tendency to treat their mobile device in a quite personal and emotional way (Chae & Kim, 2003). They prefer to access more personalized services when they are involved in mobile browsing. Spatial mobility must be considered as the major reason behind this behaviour, which is quite normal considering user’s perspective: the mobile phone is a portable, ubiquitous and exposed on everybody’s view gadget, able to signify user’s aesthetic preferences and personality.

2. Users have limited attention as they manage their mobile devices (Lee & Benbasat, 2004). This is because they usually are involved at the same time in other tasks (e.g., walking). Temporal mobility is the reason of this phenomenon.

3. Users manage their mobile devices in broadly mixed environments that are relatively unsteady from one moment to the next. Contextual mobility requires context-sensitivity on mobile device operations. So, mobile device is able to detect the user’s setting (such as location and resources nearby) and subsequently to propose this information to the mobile application. In this way, mobile device practically may offer task-relevant services and information.

Application Case: User Interfaces in M-Commerce Applications

Mobile Commerce Applications

The mobile sector is creating exciting new opportunities for content and applications developers. The use of wireless technologies extends the nature and scope of traditional e-commerce by providing the additional aspects of mobility (of participation) and portability (of technology) (Elliot & Phillips, 2004). One of the most rapidly spreading applications within the m-commerce world is the mobile Internet: the wireless access to the contents of the Internet using portable devices, such as mobile phones. Undoubtedly, delivering personalized information is a critical factor concerning the effectiveness of an m-commerce application: the organization knows how to treat each visitor on an individual basis and emulate a traditional face-to-face transaction. Thus, has the ability to treat visitors based on their personal qualities and on prior history with its site. M-commerce applications support mechanisms to learn more about visitor (customer) desires, to recognize future trends or expectations and hopefully to amplify customer “loyalty” to the provided services.

Personalized Multimedia in Interfaces of M-Commerce Applications

The goal of adaptive personalization is to increase the usage and acceptance of mobile access through content that is easily accessible and personally relevant (Billsus, Brunk, Evans, Gladish, & Pazzani, 2002). The importance of interface design has been commonly acknowledged, especially
Adaptation and Personalization of User Interface and Content

Lee and Benbasat (2004) describe in detail the influence of mobile Internet environment to the 7C framework for customer interfaces. This framework studies interface and content issues based on the following design elements: customization (site’s ability to be personalized), content (what a site delivers), context/presentation (how is presented), connection (the degree of formal linkage from one site to others), communication (the type of dialogues between sites and their users), community (the interaction between users), and commerce (interface elements that support the various business transactions) (Rayport & Jaworski, 2001). A generic personalized perspective is presented in (Pierrakos et al., 2003) with a comprehensive classification scheme for Web personalization systems. Based on all these works, we focus on multimedia design issues concerning personalized UIs for m-commerce applications. We present a reconsideration of the 7C framework from an M3 customization aspect, in which we distinguish the following mobile multimedia adaptation/personalization categories:

**M3 content** is the main category. It contains the parts of the 7C’s “content” and “commerce” design elements, which deal with the choice of media. “Multimedia mix” is the term that is used in 7C framework regarding exclusively the ‘content’ element. However, in our approach regarding mobile devices adoption: interfaces characteristics had been identified as one of the two broad factors (along with network capabilities), affecting the implementation and acceptance of mobile phones emerged (Sarker & Wells, 2003). Devices adoption is a critical aspect for the future of m-commerce, because without widespread proliferation of mobile devices, m-commerce can not fulfill its potential.
multimedia elements regarding shopping carts, delivery options etc. are also belong here because they share a lot of commons concerning adaptation and personalization. It is commonly accepted that large and high visual fidelity images, audio effects, and motion on interfaces are multimedia effects which might lead to a higher probability of affecting users’ decisions in e-commerce environments (Lee & Benbasat, 2003). However, in m-commerce setting things are different because we can not assume that the underlying communication system is capable of delivering an optimum quality of service (QoS). The bandwidth on offer and the capabilities of devices are setting limitations. Therefore, a central issue to the acceptance of multimedia in m-commerce interfaces is the one of quality. The longer the response delay, the less inclined will the user be to visit that specific m-commerce site, resulting in lost revenue. Obviously, an end-to-end QoS over a variety of heterogeneous network domains and devices is not easily assured, but this is where adaptation principle steps in.

Dynamic content adaptation of the media quality to the level admitted by the network is a promising approach (Kosch, 2004). Content adaptation can be accomplished by modifying the quality of a media object (resolution and its play rate); so, it can be delivered over the network with the available bandwidth and then it can be presented at the end device (satisfying its access and user constraints).

An essential issue for effective content adaptation is the perceptual quality of multimedia. Quality of perception (QoP) is a measure which includes not only a user’s satisfaction with multimedia clips, but also his ability to perceive, analyze, and synthesize their informational content. When a “personalization engine” is called out to adapt multimedia content, the perceptual impact of QoS can be extremely valuable, and it can be summarized by the following points (Ghinea & Angelides, 2004):

- Missing a small number of media units will not be negatively perceived, given that too many such units are not missed consecutively and that this incident is infrequent
- Media streams could flow in and out of synchronization without substantial human displeasure
- Video rate variations are tolerated much better than rate variations in audio
- Audio loss of human speech is tolerated quite well
- Reducing the frame rate does not proportionally reduce the user’s understanding (user has more time to view a frame before changes)
- Users have difficulty absorbing audio, textual and visual information concurrently, as they tend to focus on one of these media at any one moment (although they may switch between the different media)
- Highly dynamic scenes have a negative impact on user understanding and information assimilation

Another important issue regarding M3 content adaptation (both for quality and for the selection of media items), is the usage patterns for the mobile Internet. Users purchase more low-risk products (e.g., books) than high-risk ones, because they can not pay full attention to their interactions with mobile devices. Also, users tend to subscribe to content with low information intensity more than to content with high information intensity (e.g., education), because mobile devices have inferior visual displays.

Device’s constraints and personalization requirements emphasize the need for additional effective content adaptation methods. Personalization mechanisms allow customers to feel sufficiently informed about products and services they are interested in, despite the limited multimedia information delivered by a restricted display device. They can be considered as filters which reject the delivery of multimedia content
Adaptation and Personalization of User Interface and Content

that users don’t appreciate. More and more, mobile applications exploit positioning information like GPS to guide the user on certain circumstances providing orientation and navigation multimedia information, such as location-sensitive maps. To facilitate personalized adaptation, multimedia content is desirable to include personalization and user profile management information (in the form of media descriptors) (Kosch, 2004). In this way, adaptive systems can utilize information from the context (or user model) in use. Especially personalized UIs are able to exercise all kinds of personalization mechanisms (rule-based practices and simple, content-based or collaborative filtering), to locate or predict a particular user’s opinion on multimedia items.

**M3 presentation** is also an important adaptation/personalization category. It contains all parts from 7C’s “context,” “commerce,” and “connection” design elements related to multimedia presentation. M3 presentation refers to the following aspects:

- The aesthetic nature of multimedia in interfaces (i.e., the visual and audio characteristics such as color schemes, screen icons, ring melodies, etc.). These multimedia UI elements are certainly used by mobile users in order to make their phones more personal
- The operational nature of multimedia in interfaces, including internal/external link issues and navigation tools (in what ways the moving throughout the application is supported). An important issue here deals with the limited attention of users when interacting with their mobile devices. So, minimal attention interface elements, able to minimize the amount of user attention required to operate a device are welcomed. For example, utilizing audio feedback in order to supplement users’ limited visual attention is considered in general a desirable approach in mobile setting (Kristoffersen & Ljungberg, 1999). There is also an additional point to take into consideration regarding M3 presentation adaptation and personalization: how to overcome the limitations due to the lack of screen space. Certainly, visual representations of objects, mostly through graphic icons, are easier to manipulate and retain than textual representations. But, small screens need not set aside a large portion of their space for infrequently used widgets. In this context, potential adaptations can be made by substituting visual elements with non-speech audio cues (Walker & Brewster, 1999), or by using semi-transparent screen-buttons, that overlap with the main body of content in order to make the most of a small screen (Kamba, Elson, Harpold, Stamper, & Sukaviriya, 1996).

All users are not having the same context conditions and preferences. Personalization mechanisms are used for both the aesthetic and the operational nature of multimedia in interfaces. Obviously, multimedia personalization engine must be able to provide context-sensitive personalized multimedia presentation. Hence, when a distracting user setting is acknowledged, the adapted multimedia presentations on the interface should call for only minimal attention in order to complete successfully critical transaction steps. Moreover, context-awareness of mobile devices may influence M3 presentation adaptation/personalization regarding connection issues. Indeed, the recommendation of a particular external link among a set of similar ones may depend not only from its content, but also from its availability and efficiency under the specific conditions of user’s setting.

**M3 communication** contains all parts from 7C’s “communication” and “community” design elements related to multimedia. In our approach, they belong to the same adaptation/personalization category because they deal with multimedia enriched communication and interaction services.
Mobile devices are inherently communication devices. Location and positioning mechanisms provide precise location information, enabling them to better interact with applications to deliver greatly targeted multimedia communication services. The perceptual quality of multimedia and relative previously discussed issues, are also important factors for effective multimedia communication adaptation.

With M3 communication personalization, m-commerce administrators are able to make use of information about users’ mobile setting to catch the right type of multimedia communication for the right moment (taken into account also the preferences of each user about the most wanted type of communication between him or her and the site). In addition, supporting adaptive (interactive or non-interactive) multimedia communication between users enables opinion exchange about current transactions and network accesses. Undoubtedly, such functionality may provide useful information for collaborative filtering techniques, resulting in more successful personalized sites.

**FUTURE TRENDS**

Providing adaptation and personalization affects system performance, and this is an open research issue. A basic approach to improve performance is to cache embedded multimedia files. However, when personalized multimedia elements are used extensively, multimedia caching can not maximize performance. The trend is therefore to provide personalization capabilities when server-usage is light and disallow such capabilities at periods of high request. Alternatively, users can have a personalized experience, even at times of high system load, if they pay for the privilege (Ghinea & Angelides, 2004). In any case, the design of a flexible context (or user) model, capable of understanding the characteristics of mobile setting in order to facilitate multimedia adaptation and personalization processes, it appears as an interesting research opportunity.

In a multi-layered wireless Web site, more sophisticated adaptation and personalization mechanisms are introduced as we get closer to the database layer. From that point of view, multimedia database management system (MMDBMS) emerging technology may support significantly the (mobile) multimedia content adaptation process. Existing multimedia data models in MMDBMSs are able to partially satisfy the requirements of multimedia content adaptation because contain only the basic information about the delivery of data (e.g., frame rate, compression method, etc.). More sophisticated characteristics such as the quality adaptation capabilities of the streams are not included. This information would be of interest to the end user. Consequently, a lot of research deals with extending the functionalities of current MMDBMSs by constructing a common framework for both the quality adaptation capabilities of multimedia and for the modeling/querying of multimedia in a multimedia database (Dunkley, 2003; Kosch, 2004).

**CONCLUSION**

The advances in network technology, together with novel communication protocols and the considerably enhanced throughput bandwidths of networks, attracted more and more consumers to load or stream multimedia data to their mobile devices. In addition, given the limited display space, the use of multimedia is recommended so that display space can be conserved. However, mobile setting’s limitations regarding multimedia are serious. In fact, enhancing the mobile browsing user experience with multimedia is feasible only if perceptual and contextual considerations are employed.

The major conclusion of previously presented issues is that efficient delivery, presentation and transmission of multimedia has to rely on context-
sensitive mechanisms, in order to be able to adapt multimedia to the limitations and needs of the environment at hand, and even more to personalize multimedia to individual user’s preferences.

REFERENCES

KEY TERMS

Content Adaptation: The alteration of the multimedia content to an alternative form to meet current usage and resource constraints.

MMDBMS: Multimedia database management system is a DBMS able to handle diverse kinds of multimedia and to provide sophisticated mechanisms for querying, processing, retrieving, inserting, deleting, and updating multimedia. Multimedia database storage and content-based search is supported in a standardized way.

Personalization: The automatic adjustment of information content, structure and presentation tailored to an individual user.

QoS: Quality of service notes the idea that transmission quality and service availability can be measured, improved, and, to some extent, guaranteed in advance. QoS is of particular concern for the continuous transmission of multimedia information and declares the ability of a network to deliver traffic with minimum delay and maximum availability.

Streaming: Breaking multimedia data into packets with sizes suitable for transmission between the servers and clients, in order to allow user to start enjoying the multimedia without waiting to the end of transmission.

UI: (Graphical) user interface is the part of the computer system which is exposed to users. They interact with it using menus, icons, mouse clicks, keystrokes and similar capabilities.

Chapter 2.4
User Interaction and Interface Design with UML

Jesus M. Almendros-Jimenez
Universidad de Almería, Spain

Luis Iribarne
Universidad de Almería, Spain

ABSTRACT
This chapter will show you how to use and specialise UML diagrams for describing the user interfaces of a software system. In order to accomplish the description of user interfaces, the proposed technique considers three specialised UML diagrams called user-interaction, user-interface, and GUI-class diagrams, which will be built following a model-driven development (MDD) perspective. These diagrams can be seen as the UML-based UI models of the system. In addition, this chapter is concerned with code-generation to implement the user interfaces of the system by using GUI-class diagrams and user-interaction diagrams. A case study of an Internet book shopping system is introduced in this chapter to proof and illustrate the proposed user interaction and interface design technique.

INTRODUCTION
The emergence of the unified modelling language (UML) (OMG, 2005) as an industry standard for modelling systems has encouraged the use of automated software tools that facilitate the development process from analysis through coding. The user interface (UI), as a significant part of most applications, should also be modelled using UML. UML diagrams could be used to model user interfaces, and automatic CASE tools could help to generate code for user interfaces from UML designs. In general terms, visual modelling allows the developers to visualize source code in a graphical form: graphical abstractions, such as flow charts to depict algorithmic control flows and structure charts or simple block diagrams with boxes representing functions and subprograms, and so on. UML provides system
User Interaction and Interface Design with UML

architects with a visual language for specifying, constructing, and documenting the artefacts of software systems. In particular, user interfaces should be visually modelled in order to describe the behaviour of the window system in response to user interactions.

This chapter is firstly devoted to show how to use and specialise UML diagrams in order to describe the user interface and user interactions of a software system, following a particular model-driven development (MDD) perspective. Model-driven development involves creating models through a methodological process that begins with requirements and looks into a high-level architectural design. Model-driven development facilitates and improves the software analysis and design and code generation facilities from models prevent the loss of substantial information during the transition of a model to its implementation.

In our MDD perspective, we consider the following steps for user interface design and modelling:

1. Firstly, we use a UML use case diagram for extracting the main user interfaces.
2. Secondly, we describe each use case by means of a special kind of UML activity diagrams, called user-interaction diagrams, whose states represent data output actions and transitions represent data input events. This perspective allows the designer to model the user interaction (i.e., input-output interaction) in each main user interface.
3. Thirdly, each input and output interaction of the user-interaction diagrams allows the designer to extract GUI components used in each user interface. Therefore, we can obtain a new and specialized version of the use case diagram representing the user interface design, and a class diagram for GUI components: user-interface and GUI-class diagrams, respectively.
4. The user-interaction, user-interface, and GUI-class diagrams can be seen as the UML-based user interface models of the system.

This chapter will also deal with code generation techniques. In our MDD perspective, the UML-based user interface models can be used for generating executable code with the following advantages:

1. Rapid prototyping of the developed software: Software modellers would find it useful to quickly generate user interfaces from high-level descriptions of the system.
2. Model validation and refinement: Prototyping can detect fails in design and refinement and validation of model by testing user interfaces and user requirements.
3. Model-based code generation: Generated code would fit with developed models.
4. Starting point for implementers: Prototypes can be refined until final implementation.

BACKGROUND

In the literature there are some works dealing with the problem of user interfaces in UML.

Use Cases and UI Design

Some of these works (CommentEdition, 2000; Constantine & Lockwood, 2001; Nunes & Falcao, 2001; Paterno, 2001) are focused on the utilisation of UML use case diagrams as a “starting point” of the user interface design, or even as a “high-level description” of the structure of the user interface. However, there are some considerations about the use case diagram style. Following the UML philosophy, a use case diagram could not be suitable for extracting the user interfaces. Use case diagrams may include some use cases referred to parts of the system not related to user interfaces such as classes, human tasks, components of other systems interacting with us, and so on. Or even
decomposing use cases by means of include and extend relationships, one could specify specific parts of the system, which are not related with the user interface. Therefore, in our opinion, a specialized version of the use case model could be required, or even some other UML diagrams could be used to complete the use case view.

Adapting UML to UI Design

Other works (Campos & Nunes, 2005; Conallen, 1999; Heumann, 2003; Lieberman, 2004; Nunes, 2003; Nunes et al., 2001; Pinheiro da Silva & Paton, 2000) propose the introduction of new UML elements in order to model user interfaces. In this case, the need of new stereotypes or classifiers in UML in order to distinguish GUI components from other system components is well known. In this case, there is a common point of view: classes should be stereotyped with <<screen>>, <<applet>>, and <<input_form>>, to be distinguished from data classes.

In addition, there are some works (Anderson, 2000; Elkoutbi & Keller, 2000) (Elkoutbi, Khriss, & Keller, 1999) interested in the description of the logic of GUI components, using activity and state diagrams for that. In this case, user interaction can be specified by means of states, where the system shows output data and requests input data. It should be specified how the user can navigate through the user interface, opening, closing windows, picking up in links, and so on. The specified logic should describe the set of states (input, output, windows) in which the user can be found.

Code Generation and UML

With respect to code generation, unfortunately, the capabilities of code generator CASE tools to transform design to an implementation are often restricted to produce class definitions consisting of attributes and operation signatures captured in class diagrams, but not methods to implement the procedural flow within the operations. Existing approaches in this last sense turn statecharts into executable code. Statecharts are used as object controllers for specifying when an object is willing to accept request. CASE tools supporting code generation from statecharts are Statemate (Ilogix, 2006a), Omate (Harel & Gery, 1997), Rhapsody (Ilogix, 2006b), and Fujaba (Schäfer, 2002).

MAIN THRUST OF THE CHAPTER

With regard to previous works on UML (use cases) and UI design, our contribution can be summarized as follows:

• Firstly, we consider use cases as a starting point of the user interface design. Here we define a new kind of diagram, user-interface diagram: a specialized version of the use case diagram as a high-level description of the user interface.

• In addition, following the MDD perspective, we integrate this system view with a set of specialized activity diagrams for user interaction design (user-interaction diagrams). One of the benefits of this integration is that each use case in the specialized use case diagram is described by means of a specialized activity diagram, and therefore interfaces can be analyzed and built from these two models.

• In addition, a class diagram is generated from the specialized activity diagrams. GUI components can also be built from both modelling techniques.

With regard to previous works on code generation, the UI models can get prototypes of the user interface of our application. Through mapping between UML and Java, we are able to generate low-level Java code directly from the user interaction diagram. This code generation is adapted to the special case of user interfaces, which is user event-based and handles input and output data by means of special kinds of UI components.
ORGANISATION OF THE CHAPTER

The next section describes our model-driven development technique for user interfaces. The chapter continues with the technique for the code generation by using user-interface models. This chapter finishes with some conclusions and future work.

MODEL-DRIVEN DEVELOPMENT FOR USER INTERFACES

Use Case Diagrams

Use case diagrams are used as starting point for user-interface design. Use cases are also a way of specifying required usages of a system, and they are typically used for capturing the requirements of a system (that is, what a system is supposed to do). The key concepts associated with the use-case model are actors and use cases. The users and systems that may interact with the system are represented by actors. Actors always model entities that are outside the system. Use cases represent the set of tasks that the actors carry out. In addition, the “use cases” can be decomposed by means of include relationships, and they can also be related by means of generalisation/specialisation relationships that compare more general and particular tasks.

In order to design a prototype of the user interface, the use case diagram should include the system actors and the set of (main) tasks for each one in which he or she takes part. From a point of view of user interface modelling, the use case diagram can be seen as a high-level description of the main windows of the system.

To illustrate the functionality of the MDD-based technique we will explain a simple Internet book shopping (IBS) model.

In the IBS example (Figure 1), three actors appear: the customer, the ordering manager, and the administrator. A customer directly makes the purchases on the Internet, querying certain issues of the product in a catalogue of books before making the purchase. The manager deals with customer’s orders (total or partially). And finally, the system’s administrator can manage the catalogue of books by adding and eliminating books in the catalogue or modifying those already existing. The administrator can also update or cancel certain component characteristics of an order or those orders fulfilling certain searching criteria.

This information is described with a use case diagram containing the identified actors and main tasks of the system. In our case study (see Figure 1), the actors are the customer, the manager, and the administrator, and the main tasks are purchase, manage orders, manage partial orders, manage catalogue, update orders, and update partial orders.

From this use case diagram, one can identify the future windows of the system that will comply with the needs of the presentation logic (graphical user interfaces).

User Interaction Diagrams

The second modelling technique in our framework is the activity diagram. However, we need to specialise the activity diagram for user interface design in the following sense.
Our activity diagrams include states and transitions. The states represent data output actions, that is, how the system responds to user interactions showing data (or requesting them). Then the user can introduce data and the corresponding event is handled and specified by means of transitions. Transitions can be conditioned, that is, the handled event is controlled by means of condition, which can be referred to data/business logic or a previous user interaction. In other words, it is possible more than one transition from a state, and to know which of them will run depends on data/business logic or the previous user choices. We call user-interaction diagrams to this kind of activity diagrams used for user interaction description.

Now, it is supposed that each use case in the use case diagram is described by means a user-interaction diagram. However, from a practical point of view, it is convenient to use more than one user-interaction diagram for describing a use case. This is so because the logic of a use case is usually too complex. For this reason, a user-interaction diagram can be deployed in several user-interaction diagrams, where a part of the main logic is separately described. For this reason, the main user-interaction diagram can be composed of three states (i.e., “query catalogue,” “confirm proceed,” and “shopping cart”). Two of them are terminal states (i.e., “confirm proceed” and “query catalogue”). A terminal state is described in a new diagram whose states correspond to graphical elements stereotyped (for instance <<JTextField>>, <<JList>>, and <<JLabel>> stereotypes. For instance, let us focus our attention in the purchase use case. Figure 2 shows the whole user-interaction diagram modelled for the purchasing process. Initially, the behavioural description starts with an original user-interaction description (Figure 2a). The behaviour shows how the customer begins the purchasing process of querying, adding, or removing articles of the shopping cart. After a usual purchasing process, the shopping system requests the customer’s card number and an address to carry out the shipment whenever the shopping cart is not empty. This diagram shows the graphical and behavioural content of the applet window where the purchases can be carried out.

The main user-interaction diagram (Figure 2a) is composed of three states (i.e., “query catalogue,” “confirm proceed,” and “shopping cart”). Two of them are terminal states (i.e., “confirm proceed” and “query catalogue”). A terminal state is described in a new diagram whose states correspond to graphical elements stereotyped (for instance <<JTextField>>, <<JList>>, and <<JLabel>>) and labelled by a text related to the graphical element. The name of a separate user-interaction diagram should be the same as that of the state. A non-terminal state is also described in a separate user-interaction diagram containing one or more non-terminal states.

Activity diagrams describe input and output user interactions. Given that we have decided to implement our user interface by means of Java swing package, we will consider the JFrame class as a container class that opens new frame windows (if needed). In addition, graphical components can be classified as input (a text field, a button, etc) and output components (a label, list, etc). Input/output components are associated with terminal states and transitions by using the appropriate stereotype. For instance, the stereotypes JTextField, JList, JLabel are associated with states and the stereotype JButton with transitions. Since the graphical behaviour concerns with states and transitions, next we will describe them separately.

States can be stereotyped or not. Stereotyped states represent terminal states, which can be labelled by <<JTextField>>, <<JList>>, and <<JLabel>> stereotypes. For instance, let us focus our attention in the purchase use case. Figure 2 shows the whole user-interaction diagram modelled for the purchasing process. Initially, the behavioural description starts with an original user-interaction description (Figure 2a). The behaviour shows how the customer begins the purchasing process of querying, adding, or removing articles of the shopping cart. After a usual purchasing process, the shopping system requests the customer’s card number and an address to carry out the shipment whenever the shopping cart is not empty. This diagram shows the graphical and behavioural content of the applet window where the purchases can be carried out.

Transitions can be labelled by means of stereotypes, conditions, or both. For instance, a button is connected with a transition by using a <<JButton>> stereotype, and the name of the label is the name of the button. For example, a show cart transition stereotyped as <<JBut-
Conditions can represent user choices or business/data logic. The first one is a condition of the user’s interaction with a graphical component (related to button or list states), and the second one is an internal checking condition (not related to the states, but to the internal process). For example, in our case study the selections from a list are modelled by conditions. Note in the query catalogue user-interaction diagram how the results list is modelled by a <<JList>> state and a [Selected article] condition.

Figure 2 shows some transitions (i.e., [close], [exit], or [proceed]) that correspond with conditions of the user choice type. The [Exit] output transition of the state query catalogue (Figure 2a) means that the user has pressed a button called exit, which has been defined in a separate query catalogue user-interaction diagram. Nevertheless, conditions like the [cart no empty] condition are business/data logic conditions, in which the human factor does not take part.

Furthermore, stereotyped transitions (buttons in our example) and conditions connect (non) terminal states with (non) terminal states. A condition would be an output of a non-terminal state if the user interacted with a button or a list component inside the respective non-terminal state. The usual way of “condition/event” transition can connect (no)terminal states with (non) terminal states. A condition/event transition between states means which condition should be present to trigger the event. In our case study, an event can only be a button. For instance, to remove an article from the shopping cart, it must previously be selected from the cart list (Figure 2c).

User Interface Diagrams

Therefore, in our technique we have obtained a use case diagram together with a set of user-interaction diagrams, from which some correspond to use cases and others to states of use cases. How-
ever, it could be useful to have a new version of the use case diagram, to know what are the main user-interaction diagrams, that is, which are the user-interaction diagrams corresponding to use cases, and which are the secondary user-interaction diagrams, that is, which are states of use cases. For this reason, we will build a new version of the use case diagram called user-interface diagram as follows. The user-interface diagram contains the same actors and use cases of the use case diagram. In addition, we will add states (as use cases) of each use case corresponding to user interaction diagrams. In order to connect use cases, we will use the “include” or “generalisation” use case relations.

User Interface Relationships

Include and generalisation relationships have the following meaning in this user-interface diagram, similarly to the same relations in the use case diagram. If a use case contains in its user interaction diagram a state described by means of another user interaction diagram, the state is also considered as a use case, and the included state (use case) is related in the user interface diagram by the inclusion relationship with the main use case. However, this is achieved whenever the logic of the included use case is not modified by the main use case. The logic of an included use case is modified in the main use case whenever the user interaction diagram of the main use case includes transitions that are referred to internal states or conditions of the included use case. This typically happens when the main use case defines its own logic using the included use case as a piece of behaviour, but access to the included use case. Otherwise, that is, whenever the logic of the included use case is modified, we relate the main use case and the state (use case) by means of the generalisation relationship.

In addition, we have to identify a special case of generalisation relationship, in which we have a main use case including a state and the state itself is a specialisation version of another use case. This happens when the user interaction diagram of the state specialises the user interaction diagram of another use case. The specialisation consists of the replacement of states and transitions of the user interaction diagram by means of more particular states and transitions with similar semantics. Here we are interested in the identification of similarity between interactions following the same pattern; however, the difference in our case consists of several kinds of GUI components and input/output data.

In other words, the specialisation of use cases allows us to build new use cases with a more complex logic containing the specialized use case, and adding transitions and states or modifying the existent ones. On the contrary, the inclusion allows us to build new use cases with a more complex logic without adding or modifying the states and transitions of the included use case.

Given that the user interface diagram is a kind of high-level description of the user interface, the developer still could decide not to include in it all the states representing user interaction diagrams. In other words, the user interface dia-
gram represents the set of windows of the system by means of use cases. However, there could be more user interaction diagrams than windows. Usually, some user interaction diagrams can be built for deploying some states but they will not correspond to system windows.

Once user-interaction diagrams have been described, the designer proceeds to build the user interface diagram. It contains new use cases that are some of the non-terminal states of the user interaction diagrams. In addition, the developer has to identify use case relationships in the new user interface diagram as follows.

Include Relationships

Let us consider the purchasing process described in previous user-interaction diagrams. The purchase use case is a frame that includes (uses) three other frames (use cases): query catalogue, shopping cart, and confirm proceed. These use cases are described by means of separate user interaction diagrams. In addition, the logic of the use cases is not modified in the purchase user interaction diagram. It integrates the logic query catalogue diagram by checking which buttons (i.e., exit) the user pressed when he or she exits from shopping cart.

The developer can also identify an inclusion relationship between manage catalogue and withdraw article, Modify article and add article use cases (Figure 4). In these cases, four windows can be optionally opened (depending on a menu) from the manage catalogue window. In addition, the administrator identification window is mandatory opened from the Manage catalogue window in order to achieve the system's administrator tasks.

Generalisation Relationships

In order to illustrate the generalisation/specialisation relationship, we will pay attention to three use cases: purchase, query catalogue, and query catalogue by administrator. In previous sections, we have identified two cases of generalisation/specialisation.

The first case is the query catalogue and purchase case. In this case, the purchase user-interaction diagram contains a state (use case) that specialises query catalogue in the following sense. The query catalogue user interaction diagram describes how to query the catalogue of the IBS by introducing the searching criteria and showing the results. However, the purchase user interaction diagram can interrupt
the querying process by adding the searched items to the shopping cart. It is specified by adding the Add to cart button as transition from (and to) query catalogue. Therefore we can identify a specialisation relationship between purchase and query catalogue. It is also supposed that there will be a window for query catalogue from which purchase inherits.

The second case is the relationship between query catalogue and query catalogue by administrator. In this case, the administrator is supposed to have higher privileges for querying the catalogue and therefore the user interaction diagram of the query catalogue by administrator (see Figures 5 and 6) specialises in the query catalogue user interaction diagram in the following sense. The states of the query catalogue by administrator corresponding with the searching criteria and results are modified with respect to the query catalogue. It is supposed that the searching and result fields are different but the logic is similar. In other words, the query catalogue can be replaced by query catalogue by administrator given that the states can be replaced. In this case, we can identify a generalisation relationship between them. Analogously, Withdraw article and Modify article combine both kinds of specialisation, once they’ve specialized the query catalogue by administrator in the same sense that purchase specializes query catalogue, and they specialize indirectly query catalogue (see Figure 6).

The complete user interface diagram of our case study can be seen in Figure 7.

**GUI Class Diagram**

The next step of our model-driven technique consists of the building of a class diagram for GUI components. The user-interface diagrams obtained in the previous state give us the main windows. Each use case connected to an actor can be converted into a window, and if an actor
is connected to more than one use case, it can be considered a window by the actor that invokes (or embeds) each window of each use case.

Therefore, the actor window can be a menu window. In addition, in the user-interaction diagrams obtained from use cases, we have also described input and output components for data output and request and user events. It gives us the GUI components for each window. If a user-interaction diagram has a state described by means of another user-interaction diagram, we can suppose that the window of the use case could also contain a separate window for this separate task. However, now, we have to take into account the user-interface diagram and the use case relationships. In the case of inclusion, the logic is also separate, and it is possible to consider a new window. However, in the case of generalisation/specialisation, the window corresponds with a specialisation, and therefore it is better to consider a new window by using the inheritance relation.
into account the user-interface diagram and the use case relationships. In the case of inclusion, the logic is also separate, and it is possible to consider a new window. However, in the case of generalisation/specialisation, the window corresponds with a specialisation, and therefore it is better to consider a new window by using the inheritance relation.

The windows obtained from use cases and the GUI components obtained from each user-interaction diagrams allow us to build a class diagram, which we call GUI-class diagram, where there are windows classes connected by associations or by inheritance. In addition, there are GUI component classes connected by associations to window classes.

Once the user-interface diagram has been built and a set of user-interaction diagrams has been obtained, now we can generate a GUI-class diagram. The GUI-class diagram is built from Java swing classes. In the method, each use case corresponds with a frame class. Use cases are translated into classes with the same name as these use cases. The translated classes specialise a Java Frame class. The components of the frame (use case) are described in user-interaction diagrams. A terminal state is translated into that Java swing class represented by the stereotype of the state. The Java swing class is connected from the container class. For example, those terminal states stereotyped as <<JTextField>> are translated into a JTextField class in the GUI-class diagram. Something similar happens with the rest of stereotyped states and transitions. Figures 8 to 12 show the main classes of GUI-class diagram of the customer’s side.

As it can be seen in these figures, the stereotyped states and transitions in the user-interaction diagrams are translated into Java classes in the GUI-class diagram. The stereotype name of a transition or state is translated into the appropriate Java swing class. For example, the <<JButton>> stereotype of the Proceed transition that appears in the purchase user-interaction diagram (see Figure 2a) is translated into a JButton class.
The windows obtained from use cases and the GUI components obtained from each user-interaction diagrams allow us to build a class diagram, which we call GUI-class diagram, where there are windows classes connected by associations or by inheritance. In addition, there are GUI component classes connected by associations to window classes.

Once the user-interface diagram has been built and a set of user-interaction diagrams has been obtained, now we can generate a GUI-class diagram.

The GUI-class diagram is built from Java swing classes. In the method, each use case corresponds with a frame class. Use cases are translated into classes with the same name as these use cases. The translated classes specialise a Java Frame class. The components of the frame (use case) are described in user-interaction diagrams. A terminal state is translated into that Java swing class represented by the stereotype of the state. The Java swing class is connected from the container class. For example, those terminal states stereotyped as <<JTextField>> are translated
into a JTextField class in the GUI-class diagram. Something similar happens with the rest of stereotyped states and transitions. Figures 8 to 12 show the main classes of GUI-class diagram of the customer’s side.

As it can be seen in these figures, the stereotyped states and transitions in the user-interaction diagrams are translated into Java classes in the GUI-class diagram. The stereotype name of a transition or state is translated into the appropriate Java swing class. For example, the <<JButton>> stereotype of the Proceed transition that appears in the purchase user-interaction diagram (see Figure 2a) is translated into a JButton class.

GUI Prototypes

Finally, rapid GUI prototypes could be obtained from the GUI-class diagram. Figure 13 shows a first visual result of the purchase window. Note how the purchase window is very similar to the query catalogue window, except that the second one includes three buttons more than the first window. This similarity between windows was revealed in the user interface diagram as a generalisation relationship between use cases: between the query catalogue and purchase use cases. In the IBS design, the customer will always work on a purchase window opened from the Customer window, and never on a query catalogue window, though the former inherits the behaviour of the latter (i.e., by the relation of generalisation). Let us remark that purchase inherits from query catalogue, and that the five windows (GUI) are the five use case of the client side (see Figure 3).
The shopping cart window (Figure 13c) appears when the show cart button is pressed on the purchase window (Figure 13b). Note in the user interface diagram, shown in Figure 7, how the button is associated with the window by means of an inclusion relation between use cases. On the other hand, the two information windows (Figure 13d) are also associated with two buttons: the remove article button in the shopping cart window and the proceed button in the purchase window. Note again how these windows are also described as inclusion relations between use cases.

Moreover, observe the user-interaction diagrams shown in Figure 2 to better track the behaviour of the example. To develop the example, we have used the Rational Rose for Java tool. For space reasons, we have only included a part of the GUI project developed for the case study. A complete version of the project is available at http://indalog.ual.es/mdd/purchase.

CODE GENERATION FOR USER INTERFACES

Finally, our model driven technique allows us to obtain code generation from the developed models. The user-interaction diagrams describe each user interaction of each use case by means of states representing data output and transitions representing data input and events.

Code generation consists of coding an event-based user interface. We have decided to implement our user interface by means of the Java swing classes, and therefore we will use Applet and Frame classes for window components, and button, label, list, etc., for other UI components. According to the Java swing package, events are handled by means of listeners and event handlers in the corresponding window classes.

In order to explain the transition of the user interaction diagrams to code, we should first track a real interaction of the users with windows from the example: the purchase behaviour from the client side.

Here we can see the complete sequence of user/windows interaction. The first window (purchase, slide 1) shows ten graphical components: two labels (searching criteria and results), one text field (textfield), one field with a list of results (results), and six buttons. As we can see, the search, close and exit buttons are enabled whereas buttons add to cart, show cart, and proceed are not active. The user can only choose one searching criteria in the corresponding field and then click search. This interaction with the window after clicking the button makes the user access the logic data to obtain the results and then he or she gets to slide 2 window.

In that window (slide 2), we can observe that the searching button has been deactivated and the user can choose either one element from the list or exit the application or clear the searching criteria, in which case the search button is again activated. Following the usual interaction sequence, when the user is in the slide 2 window, he or she can choose one item from the list and then he or she will go to slide 3.

Moreover in slide 3, one button to add the cart is activated. The user adds to the cart the selected element by pressing the button and then he or she gets to the slide 4 window. In this state, there are some buttons that can show, on the one hand, the content of the cart (show cart) and on the other hand, they can make the purchase (proceed). The user can choose different elements from the list and add them to the cart. He or she can also enter new elements to the cart from a new searching, clearing the list (clear), and entering a new “searching criteria” (slide 5). In this state, we can observe that the searching button is activated and the adding to cart button is deactivated. However, show cart and proceed buttons are not activated because the cart is not empty and the user at any time can see the cart or make the purchase. If the user wishes to see the content of the cart, he or she would get to the slide 6 window (shopping cart).
User Interaction and Interface Design with UML

Figure 14. All complete sequence of the purchase interaction

![Sequence of purchase interaction](Figure14.jpg)

This new window (slide 6) has two labels, one list and two buttons; the first one is deactivated to avoid the removal of an element from a list until the user hasn’t selected one of them and the second one allows us to close the window.

If the user selects one element from the list (slide 7), the button to eliminate it from the cart is activated. If so, he or she would get to the third level of the window for requesting the user’s confirmation to eliminate the element from the cart (slide 8).

If the user confirms the elimination (in window slide 8) he or she would get to the last level of the window shown in slide 9; otherwise, he or she would get to the slide 7 again.

General Structure of Frame Classes

The interaction behaviour previously described is defined by the designer through user-interaction and user-interfaces diagrams. The relationship of dependences between windows is described.
Figure 15. A summary for the user-interface and user-interaction diagram of the purchase function

by means of user-interfaces diagrams (see again Figure 3).

The behaviour of the window when the user activates and deactivates buttons and changes the state of the graphical components is described by means of user-interaction diagrams (see again Figure 2). In order to obtain the behaviour shown in Figure 14, modelling it with user-interface and user-interaction diagrams (Figures 2 and 3), we create code prototypes in Java from these diagrams, making them correspond with specific lines of Java code. The most general structure of our method is the Frame classes for the windows of the system.

To explain how to make this relationship between diagrams and code, we are focusing on the purchase user-interaction diagram. Figure 15 shows three perspectives of the purchase:

1. The user-interface perspective, where the designer studies the dependences between windows through use cases;
2. The user-interaction perspective, where the designer models the behaviour of the graphic components of the windows and their interaction with the user; and

3. The GUI perspective, where the user works with a rapid prototype of the windows through a rapid generation of the code from both aforesaid perspectives (as previously seen).

In a symbolic way, we have represented in the picture the GUI perspective (of the windows) with its equivalent in the user-interface perspective, including the type of relationship between windows (in order to clarify the dependences between them).

In this example, these five use cases lead to five Java files of frame type. Their names are obtained from the use case name (which will be the same as the one for the user-interaction diagram, one per use case). If compound nouns exist then a simple name is created with the initials of each word in capital letters (Table 1).

Classes extend JFrame class and present a general structure of implementation based on frames (see Table 2). The basic structure of frame prototype created in the diagrams-to-code transition, is composed of four sections: one heading, one class constructor, one initiator of the frame (jbInit) and one basic prototype of the implementation of the detected methods (related with the logic of presentation). In the heading (labelled with /** @GUIcomponents */) the attributes are considered to be graphical components that have been detected in the corresponding user-interaction diagram. The class constructor is the same for all code files created (except for the name of the constructor). In the initiator of the frame (jbInit) it is included the code lines that model the graphical content of the window. The designer should establish the position and size of the graphical components of the frame later on, as the code generated is just a prototype of the window. In the fourth section of the Frame, it is created the basic methods related to the interaction of the user with the graphic elements that he or she can interact with: buttons, lists, and text fields.

**GUI Components**

In order to analyze how translating the diagrams components to code inside the frame, we’ll again use the purchase example in Figure 15.

The behaviour of the purchase window begins with the initial state query catalogue (represented
by the designer as an inheritance of behaviour in the user-interface diagram. As it can be observed, the purchase window inherits all the graphical components (and behaviour) of the “query catalogue” window and it also adds the add to cart, show cart and proceed buttons, which are not activated. From the initial state query catalogue, the four out coming transitions correspond to interactions with the buttons of the window and deal to new states. What the diagram shows from its initial state is the following: If there is an element selected from the list, then it is activated the button to add one element to cart.

```java
<<JButton>>
[ selected article ] / Add to cart
```

If the cart is not empty ([cart not empty]) it is activated the button to show the content of the cart and make the purchase of the products in the cart.

```java
<<JButton>>
[ cart not empty ] / Shopping cart
```

```java
<<JButton>>
[ cart not empty ] / Proceed
```

The transition [exit] in the initial query catalogue state, corresponds with the operation of clicking on the exit button inside the behaviour diagram of the window (frame): query catalogue (window inherited by purchase). The same happens with the other two transitions that reach this initial state from the state Confirm proceed (window to confirm the purchase).

For this example, there are four modelled graphical components: labels, text fields, lists, and buttons. In Table 3, it is shown the correspondence between graphic components of the user-interaction diagram (stereotypes) and the code generation.

In Table 3, column “sterotype” represents the stereotypes used in the states/transitions of the user-interactions diagram.

The columns “attribute” and “class” represent the name of the attribute and the base class instantiated in the code generated. The criterion followed to establish the name generated in the code is: name_Type. That is, as a name it is used the same name indicated in the interaction diagram in capital letters, followed by a hyphen (i.e., “_”) and then finished by base type (label, button, list, etc.). If the original name has blanks

<table>
<thead>
<tr>
<th>UI diagrams</th>
<th>Code generation</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
<tr>
<td>&lt;&lt; JButton &gt;&gt;</td>
<td>name</td>
</tr>
<tr>
<td>[condition]</td>
<td>None</td>
</tr>
</tbody>
</table>
in between, they are substituted by hyphens. For example, the label:

```
<<JLabel>>
```

Shopping cart

It is translated to the name of the attribute shopping cart button and then it is generated the following Java code:

```java
public JLabel shopping_cart_Button = new JLabel();
```

The “in/out” column represents an exit from/to the user (or window). So, for example, one stereotype label will represent a text shown from the system towards the user (window) whereas the button (according to its graphic behaviour) represents an income action (interaction) from the user towards the system. The “textfields” and lists stereotypes represent both options: the system shows and modifies the content of these graphic components and at the same time, the user can either write (textfield) or choose (list) in these graphic components. The “out” components have no correspondence with the code, whereas the “in” components have correspondence with one listener class.

The “listener” column indicates whether a graphical component is moved by means of a listener class. This type of class allows the class creating it for listen the behaviour of the graphic component with the user. It is usual to use listener in buttons and lists (we’ll study these later).

The “S/T” column is referred to whether the graphic component corresponds with a state or a transition in the user-interaction diagram.

Finally, “markup” column is referred to the mark prototype created before the translated code. This mark helps to identify the content of the text when the programmer has to rewrite or insert the new code to add and complete the functionality of the windows.

### Mapping States into Code

As previously said, the states of a user-interaction diagram can be referred to terminal states (label, textfield, list) and non-terminal states

#### Non-Terminal States

Let us begin with the user-interaction diagram purchase (see Figure 15). The diagram is composed of three non-terminal states. We should remember that a non-terminal state is a state
For a label case, three basic code lines are generated: one in the heading to define the type (JLabel) and two in the initiation (jbInit) to establish the component. In Figure 16, it is shown a bit of code generated to the label state "confirm remove article." The code line 3 creates one variable of JLabel type. Note how the name of the variable is obtained from the name given to the <<JLabel>> state in the user-interaction diagram. The line 7 establishes the text that will appear in the window. Line 9 adds the label to the container. Lines 2, 6, and 9 are marks established previously that are inserted in the code to facilitate the identification of each part of the code.

Table A.2 of Appendix A shows the Java code pattern that is translated from the <<JLabel>> graphical components of user-interaction diagram.

For the "text fields," five basic code lines are generated. Two of them are generated in the heading to define two graphical components in the heading: one JTextField and one JLabel to name it in the window. The other three code lines are generated in the initiation section of Figure 18. The results list state in query catalogue

```java
1: public class QueryCatalogue extends JFrame {
2:   /** @GUIcomponents */
3:   public JLabel searching_criteria_Label = new JLabel();
4:   public JTextField searching_criteria_TextField = new JTextField();
5:   
6:   private void jbInit() throws Exception {
7:     /** @Label */
8:     name_Label.setText("Searching criteria");
9:     
10:    /** @Panel */
11:    this.getContentPane().add(searching_criteria_Label, null);
12:    this.getContentPane().add(searching_criteria_TextField, null);
13:  } // end jbInit()
14: }
```

```java
1: import javax.swing.event.*;
2: 
3: public class QueryCatalogue extends JFrame {
4:   /** @GUIcomponents */
5:   public JLabel results_Label = new JLabel();
6:   public JScrollPane results_ScrollPane = new JScrollPane();
7:   public JList results_List = new JList();
8:   
9:   private void jbInit() throws Exception {
10:     /** @Label */
11:     results_Label.setText("Results");
12:     
13:     /** @List */
14:     results_ScrollPane.getViewport().add(results_List, null);
15:     results_List.addListSelectionListener(
16:         new javax.swing.event.ListSelectionListener () {
17:             public void valueChanged(ListSelectionEvent e) {
18:                 results_List_ShoppingCart_GUI(); }
19:         });
20:     
21:     /** @Panel */
22:     this.getContentPane().add(results_Label, null);
23:     this.getContentPane().add(results_ScrollPanel, null);
24:  } // end jbInit()
25: 
26: // Methods ...
27: void results_List_ShoppingCart_GUI() { ... }
28: }
```
whose behaviour is defined separately from other diagram of interaction. For example, the query catalogue, confirm proceed, and shopping cart states will be defined in independent user-interaction diagrams having the same name as the corresponding state. In the user-interface diagram, the query catalogue is established by the designer as an inheritance for purchase, whereas the other two states (which are “use cases” and therefore windows) are established as conclusions in the user-interface diagram (i.e., <<include>>). The translation is as follows:

```java
public class purchase extends querycatalogue {
    /** @GUI */
    ShoppingCart shoppingcart_GUI = new ShoppingCart();

    /** @GUI */
    ConfirmProceed confirmproceed_GUI = new ConfirmProceed();
    ...
```

Note that purchase class inherits querycatalogue in the code. The two “include” relationships are included in the code in the heading section (one of the four that frame has). On the code line a @ GUI mark is inserted to trace an inclusion of the window in the process of translation. Moreover, the criterion for the name of the GUI variable is considering the original name of the included window followed by “_GUI.”

Terminal States

Terminal states (label, list, textfield) are translated into code lines in the heading, initiation of Frame (jbInit) and implementation of methods sections (only in list). Appendix A contains the Java code patterns translated from the graphical components of the user-interaction diagram. Let’s see each of them separately.

For a label case, three basic code lines are generated: one in the heading to define the type (JLabel) and two in the initiation (jbInit) to establish the component. In Figure 16, it is shown
a bit of code generated to the label state “confirm remove article.” The code line 3 creates one variable of JLabel type. Note how the name of the variable is obtained from the name given to the <<JLabel>> state in the user-interaction diagram. The line 7 establishes the text that will appear in the window. Line 9 adds the label to the container. Lines 2, 6, and 9 are marks established previously that are inserted in the code to facilitate the identification of each part of the code.

Table A.2 of Appendix A shows the Java code pattern that is translated from the <<JLabel>> graphical components of user-interaction diagram.

For the “text fields,” five basic code lines are generated. Two of them are generated in the heading to define two graphical components in the heading: one JTextField and one JLabel to name it in the window. The other three code lines are generated in the initiation section of frame (jbInit). For example, Figure 17 shows how translating the terminal state searching criteria (in the user-interaction diagram of frame query catalogue) into a code in two components (lines 2 and 3). It is created a “text field” area (JtextField) and a text (label) which accompanies the text field. For the naming of the variables we use the same criterion established before: the same text that appears in the state followed by “label” or “textfield”. In line 9, it is established the text in the window. Lines 11 and 12 add both graphical components to the container.

Table A.3 of Appendix A shows the Java code pattern that is translated from the <<JtextField>> graphical components of the user-interaction diagram.

Finally, there are the terminal states of list type. Graphically these states are somehow special since—like a textarea—they can be translated into different ways: a label component, other list or even a scrollpane. The latter can be used as a container to show the elements from the corresponding list. Several lines are generated in the translation, in three sections (heading, initiation, and methods). For example, Figure 18 shows a translation of the results state.

Lines 5, 6, and 7 are generated in the heading (after /** @GUIcomponents */) defining the name of the variables of the three graphical components. Again the criterion used for the naming of the variables is the same as that one used in previous examples. In the initiation section (jbInit) the following code is created. Firstly, the label text is established in the panel (line 11). Then, an event of listener type is used to catch the interactions of the user with the list when he or she presses the elements of the list. Therefore, in line 14, there is the container JScrollPane type where the list is and from lines 15 to 18 there is the listener event on the list. To do so, the library javax.swing.event.* is imported (line 1). Lines 21 and 22 add graphical elements to the panel. Finally, the method implementation section (line 26) includes the prototype of the method used each time the user presses on an element from the list. The implementation of the method is a later task of the programmer.

In table A.3 of Appendix A it is shown the Java code pattern translated from JList graphical components of user-interaction diagram.

Mapping Transitions into Code

Transitions correspond with buttons (<<JButton>>) or changes in the internal state of the data logic. They are represented in the diagram as a condition markup (p.e., [cart not empty] o [Close]). Table A.1 (Appexd A) shows the Java code pattern for a graphical component <<JButton>> translated from the user-interaction diagram.

Transitions represent graphical components that generate code at several sections of the program. The translation into code is the more important issue in the code generation process, since it reveals the usefully of the user-interaction diagrams for the traceability of the interaction of the user with the graphical components of the
window and also how that (window) responds to the user. To explain the translation of states to code, we will use again the purchase windows sample. In Figure 19, we show (at the right side) the two related user-interaction diagrams of the purchase window (showed at left side).

Remember that the system’s designer has described the purchase window from the query catalogue window, which represents a state in the user-interaction diagram of the purchase window. This state inherits the inner behaviour of the query catalogue (whose behavioural interaction is shown at the right-lower side in Figure 19). It arrives at two possible states through four transitions from the state query catalogue: (a) see the state of the cart (shopping cart state); or (b) carry out the purchase of the products stored in the cart (confirm proceed state). Both states are reached from the purchase window through the buttons show cart and proceed. In the state, a conditioned transition has been included for reaching these two windows from purchase: that the cart is not empty. In other words, a conditioned button-transition corresponds with an operation of activation/deactivation of buttons.

Since these three buttons are conditioned by a selection action in a list, a listener operation is generated on the list in the purchase class. Remember that both the list and the most of the graphical components of the purchase window are inherited from query catalogue window (i.e., public class purchase extends querycatalogue), and therefore the operation listener is done on the superclass, which contains the list.

In this way, whenever the user presses on the list, an event is captured, which calls to the function selected_articles_list_querycatalogue_GUI(). The name of the method is established by the text included in the condition of the transition in the user-interaction diagram. For instance, a button-transition Add to cart containing a condition [selected articles] means that the class (frame) purchase enables the button Add to cart in the window if and only if an element of the list has been selected; in other case, the button will remain disabled (see Figure 19). In case of exist a selected element in the list, the button is activated and the transition leads again to the same state, to include the selected element (and others) to the list. This generates the following lines of code for the method on the listened element.

```java
/** @List */
public class purchase extends querycatalogue {
    /** @GUIcomponents */
    public JButton add_to_cart_Button = new JButton();

    private void jbInit() throws Exception {
        /** @Button */
        name_Button.setText("Add to cart");
        name_Button.addActionListener( 
            new java.awt.event.ActionListener() { 
                public void actionPerformed(ActionEvent e) { 
                    add_to_cart_Button_Purchase_GUI(); 
                } });

        /** @Panel */
        this.getContentPane().add(add_to_cart_Button, null); 
    } // end jbInit()

    // Methods ...
    /** Button */
    void add_to_cart_Button_Purchase_GUI() {
        ... 
    }
}
```

The activation of the button (add_to_cart.Button.setEnabled) implies the button has been before declared in the panel, created and added.
Following the trace of the example, the other two button-transitions that leave the state *query catalogue* remain disabled until the cart is not empty (button *Add to cart*):

```java
/** @Button */
public void add_to_cart_Button_purchase_GUI() {
  show_cart_Button.setEnabled(true);
  proceed_Button.setEnabled(true);
}
```

Once the buttons is activated, two other states can be reached from the state *query catalogue*: (a) the state *shopping cart*, whether the button *show cart* is pressed; or (b) the state *confirm proceed*, whether the button *proceed* is pressed. Since both states are not stereotyped, they are translated into two independent windows (frames) with independent behaviours in *user-interaction diagrams*, also independent (i.e., with an initial state and another end state).

Nevertheless, this encapsulated behaviour (i.e., a *user-interaction diagram*) can be interrupted by means of conditioned simple transitions (or simply “simple transitions”). Simple transitions are those transitions that are labelled only by a condition (p.e., [screen], [accept], [close], and [exit]). These transitions refer to an action of pressing a button that exists inside the non-terminal state (a window). For instance, the button-transitions [accept] and [screen] refer that, being in the state (frame) *confirm proceed* the user presses one of these buttons, and one returns to the state (frame) *query catalogue*. The same for the transition [close].

Nevertheless, there is a special case of simple transition: that one that does not come from another state, but it departs from the target state. For example, the simple transition [exit] means that there has been pressed the button exit inside the frame *query catalogue*, whose behaviour is defined in another independent *user-interaction diagram* (in which the button is defined). In any case, both the simple-transitions of the type [accept] or of the type [exit] the interpretation in the code is reflected by means of a *listener* operation on those buttons of the window (class) containing the buttons, that interrupts the normal interaction sequence of the above mentioned class.

```java
public class purchase extends querycatalogue {
...
  private void jbInit() throws Exception {
...
    // Listener on children
    /** @Button */
    shoppingcart_GUI.close_Button.addActionListener(
        new java.awt.event.ActionListener() {
          public void actionPerformed(ActionEvent e) {
            close_Button_ShoppingCart_GUI();
          }
        });
  }
  /** @Button */
  confirmproceed_GUI.accept_Button.addActionListener( ...);
  /** @Button */
  confirmproceed_GUI.cancel_Button.addActionListener( ...);
}
```

Appendix B partially shows the java code of one of the five classes of the project example: the class *ShoppingCart*. This information is available in the following Web page: http://indalog.ual.es/mdd/purchase.

**CONCLUSION AND FUTURE WORK**

In this chapter, we have studied a model-driven development technique for GUI design. We have defined a new kind of UML diagram (i.e., the *user-interface diagram*), which specialises in the use case diagram for user interface design. In addition, we have shown how to describe use cases by means of specialized activity diagrams (*user-interaction diagrams*) in order to specify the user interface of each use case. Finally, we have shown how to generate class diagrams for GUI and how to build rapid prototypes for the user interface. As future work, we plan to study the following extensions of our work:
1. Integrate the user interface view with the data and business logic;
2. Incorporate our method in a CASE tool in order to automate it;
3. Integrate our technique in the whole development process.

ACKNOWLEDGMENT

This work has been partially supported by the Spanish project of the Ministry of Science and Technology TIN2005-09207-C03-02 and TIN2006-06698 under FEDER funds.

### APPENDIX B. THE SHOPPING CART FRAME

```java
public class ShoppingCart extends JFrame {

    /** @GUIcomponents */
    public JLabel shopping_cart_Label = new JLabel();
    public JLabel selected_articles_Label = new JLabel();
    public JButton remove_article_Button = new JButton();
    public JButton close_Button = new JButton();
    public JScrollPane selected_articles_ScrollPane = new JScrollPane();
    public JList selected_articles_List = new JList();

    /** @GUI */
    ConfirmRemoveArticle confirmremovearticle_GUI = new ConfirmRemoveArticle();

    public ShoppingCart() { // Constructor }

    private void jbInit() throws Exception {
        /** @Label */
        shopping_cart_Label.setText("Shopping Cart");
        ...
        /** @Button */
        remove_article_Button.setText("Remove article");
        remove_article_Button.setEnabled(false);
        remove_article_Button.addActionListener(new java.awt.event.ActionListener() {
            public void actionPerformed(ActionEvent e) {
                remove_article_Button_ShoppingCart_GUI();
            }
        });
        ...
        /** @List */
        selected_articles_ScrollPane.getViewport().add(selected_articles_List, null);
        selected_articles_List.addListSelectionListener(...);
        /** @Panel */
        this.getContentPane().add(close_Button, null);
        ...
        /** Listener on children */
        confirmremovearticle_GUI.cancel_button.addActionListener(...);
        confirmremovearticle_GUI.accept_button.addActionListener(...);
    }

    /** @Button */
    void remove_article_Button_ShoppingCart_GUI() {
        this.setEnabled(false); confirmremovearticle_GUI.setVisible(true);
    }

    /** @Button */
    void close_Button_ShoppingCart_GUI() { this.setVisible(false); }

    /** @List */
    void selected_articles_List_ShoppingCart_GUI() {
        remove_article_Button.setEnabled(true);
    }

    /** @Methods children */
    void cancel_button_ConfirmRemoveArticle_GUI() { this.setEnabled(true); }

    /** @Button */
    void accept_button_ConfirmRemoveArticle_GUI() { this.setEnabled(true); }
}
```

Chapter 2.5
Design Methods for Experience Design

Marie Jefsioutine
University of Central England–Birmingham, UK

John Knight
University of Central England–Birmingham, UK

ABSTRACT

The following chapter describes an approach to Web design and evaluation where the user experience is central. It outlines the historical context in which experience design has evolved and describes the authors’ experience design framework (EDF). This is based on the principles of user-centred design (UCD) and draws on a variety of research methods and tools to facilitate the design, development, and evaluation of user experiences. It proposes that to design usable, accessible, engaging, and beneficial Web sites, effort needs to focus on visceral, behavioural, reflective, and social factors, while considering contexts such as the who and why; what and how; when and where; and with what of Web site use. Research methods from a variety of disciplines are used to support exploration, communication, empathy, and speculation. Examples of the application of the EDF, to various stages of the Web design process, are described.

INTRODUCTION

Although change is afoot, designers (including design engineers)—still worry that corporate bosses and clients see them as merely ‘making things pretty.’

— Molotch, 2003, p. 28

Producing Web sites is a process that involves a range of skills and disciplines. Design is not an add-on to make the screens look good. Design impacts on what people do, how they do it, and with whom they do it. Products, whether they are Web sites, toasters, or services embody a range of values and our interaction with them is a form of communication. When interacting with a Web site, for example, we may be communicating with other people, real or imagined. As we type with the keyboard, we hear and feel the keys and may vent our frustration through the force of our tapping. While reading the words on a screen we are also taking in all kinds of nonverbal messages...
from the layout—images, colours, fonts, icons, language, and style of language. Our experience is also affected by our surroundings, our memories of past actions, our current knowledge, and our expectations of the future.

Interaction with a Web site is mediated by a network of people, machines, and systems. The Internet works because of the design of protocols, browsers, laws, technical standards, security mechanisms, machines, communication technologies, and physical infrastructure as much as it does because of the design of the Web pages. Our experience of a Web site is therefore a product of our personal understanding of its context. Givechi and Velázquez (2004) describe the “positive space” of a product, which becomes more significant than the product itself, “the aura of a product, the sum of its physical attributes plus its intangible essence—or the meaning it hosts for each of its users” (p. 43). The meanings we attach to a product change with time, in part due to our changing experiences, the wider socioeconomic and political context of a product, and our changing expectations. To build a successful product, a designer needs to be aware of as many of these factors as possible, and this is why a consideration of the whole user experience is important.

FROM SOFTWARE ENGINEERING TO EXPERIENCE DESIGN

Concepts like “user experience” and “design of experience” are common in the design and business communities now (Fulton-Suri, 2004, p.14), but this has not always been the case, and in some software development circles designer still has negative connotations. It is important to recognise the context in which Web design has emerged, to understand why these concerns are so topical.

The development of computer software and interfaces in the 1960s emerged from fields traditionally associated with engineering and science. This era was typified by optimism for technology, and even in the traditional design disciplines there was a movement towards rationalising design methods. Hailed as the “design science decade” (Fuller, 1969, p. 305) the emphasis was on objectivity, rationalism, and technology.

The term software engineering can be traced back to an international conference convened by NATO in 1968, to solve the “software crisis” (Campbell-Kelly & Aspray, 1996, p. 200). The crisis emerged from large scale (often military) software projects that encountered problems in management and quality. In response to these failings a number of risk management strategies were advocated including the waterfall development lifecycle. Here design and development flowed through a predetermined course of phases. The formalised nature of the process was predicated by each phase having specified inputs and outputs, which could be checked along the way.

A design approach based purely on linear, logical problem solving did not work for the new technologies (e.g., computing, software, and solid state electronics), where problems were nebulous and constantly evolving through technological development and changing requirements. Brooks’ (1975) experience on IBM’s System/360 project was typical. He describes how software defied traditional logical engineering approaches. Even increasing resources did not improve the success of the approach.

In design disciplines such as product design and architecture, there was a growing realisation that some problems were unsolvable by logical deduction (Cross, 2001). Rittel and Webber (1973), for example, contrasted the “wicked problems” of design with the “tame” ones of science and engineering. In software design attention was turning to human factors. Whereas traditional engineering and industrial design focussed largely on external and measurable ergonomic factors, computer interaction required an understanding of internal, cognitive aspects. In 1969 the International Journal of Man Machine Studies was launched.
and a new field emerged, looking at what is now called human-computer interaction (HCI).

The idea that the computer interface could be modelled on human needs rather than driven by system capabilities led to the development of the graphical user interface (GUI) launched with one of the early commercially available personal computers, the Xerox Star, in 1981. Although the product itself was not successful, the concept of the GUI became almost universally adopted. This interface had been developed using usability engineering methods, including paper prototyping and testing on potential users. The design process was iterative and responsive.

In 1985, Gould and Lewis codified their own approach to software development, identifying the following key principles: early focus on users and tasks; empirical measurement through early and continual user testing; integrated design; and iterative design (Gould 1995; Gould & Lewis, 1985). UCD, as it came to be called, is now embodied in international standards for software development. International Organization for Standardization (ISO, 1999) 13407, for example, describes it as:

an approach to interactive system development that focuses specifically on making systems usable. Whatever the design process the allocation of responsibilities and roles adopted, the incorporation of a human-centred approach is characterised by the following:

a. the active involvement of users and a clear understanding of user and task requirements;

b. an appropriate allocation of function between users and technology;

c. the iteration of design solutions; and

d. multidisciplinary design.

Usability became a high profile issue in the 1990’s (see Knight & Jefsioutine, 2002) and much of the HCI literature aimed at supporting interaction designers, focused on cognitive and behavioural models of human interaction with attempts to formalise methods (e.g., Harrison & Thimbleby, 1990) and generate guidelines about human behaviour, much like the rational approaches to design.

The relationship between humans and computers is not entirely rational or logical however. Reeves and Nass (2002), for example, describe the ways in which people treat computers and software like real people with feelings and personalities. Jordan (2000) argues that usability is no longer sufficient as a design goal. He argues that customers now expect products to be easy to use and claims that “usability has moved from what marketing people call a ‘satisfier’ to being a ‘dissatisfier’” (Jordan, 2000, p. 3). People no longer notice when a product is usable, just when it is difficult to use. Fulton-Suri (2004) points out “established products have become more similar in technology, functionality, price and quality, companies have turned to design to differentiate, their offerings…to create stronger emotional connections with their customers” (p. 13). Lastly, the notion of a problem that can be identified and solved through logical deduction is often at odds with how successful products are developed and adopted by consumers.

The challenge for Web designers is no longer just to produce a functioning and usable product, they must now meet the needs of an increasingly sophisticated and demanding audience and a competitive market place. The EDF was developed by the authors to address these challenges by collating useful methods and approaches to designing products like Web sites and by considering the whole user experience (Jefsioutine & Knight, 2004).
THE EXPERIENCE DESIGN FRAMEWORK

The EDF advocates the principles of UCD already described, and adds another set of considerations: qualities, dimensions of experience, research contexts, and research methods. These are described hereafter.

Qualities

Each product will have its own specific user requirements. The EDF proposes that four fundamental qualities underlie these requirements.

Usable

To go beyond usability does not mean that it is no longer necessary. The benefits of usability are well documented (e.g., Bevan, 2000). Usability is defined as “the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use” (ISO, 1998) and “the capability of the software product to be understood, learned, used and attractive to the user, when used under specified conditions” (ISO, 2000). Indeed, in long-term use of a product, there is evidence that usability becomes more important than style in predicting users’ satisfaction (Maguire, 2004). Usability cannot be ignored as a design goal.

Accessible

The Web relies on a level of standardisation such that pages can be accessed by anyone, on whatever browser or device they use, be it a PC, Mac, or mobile phone. As the Web has grown, so have the standards and so have the number of inaccessible Web sites. Despite the publication of guidelines for accessible web design by the World Wide Web Consortium (W3C, 1999), a survey of Web designers found that difficulty interpreting guidelines was a major barrier to implementing them (Knight & Jefsioutine, 2003). Furthermore, the UK’s Disability Rights Commission (2004) found that nearly half of the usability and accessibility problems were not violations of any of the WCAG’s checkpoints. DiBlas, Paolini, Speroni, and Capodieci (2004) argue that “W3C guidelines are not sufficient to ensure an efficient—even less satisfactory—Web experience” (p. 89). It is important that accessibility is seen as part of the user experience rather than a series of technical checkpoints to cover.

Figure 1. The experience design framework (Jefsioutine & Knight, 2004)
Engaging

Shedroff (2001, p. 4) suggests an experience comprises of “an attraction, an engagement, and a conclusion”. What attracts someone to a product could be a need to perform a task, an aesthetic quality, or an affordance. The engagement is then sustained over a period of time, beyond the initial attraction. Csikszentmihalyi (1991) describes the experience of optimal experience and flow: “Concentration is so intense that there is no attention left over to think about anything irrelevant, or to worry about problems. Self-consciousness disappears, and the sense of timing becomes distorted” (p. 71).

Although this level of engagement may not be appropriate for all products, it is useful to consider the properties of an experience that make it engaging. Fiore (2003) suggests that an experience includes a number of dimensions: it is educative and memorable; whole, unique and nonreproducible; historical; meaningful/aesthetic; contextual; physical/sensual/embodied; and situated in time and space. Jones, Valdez, Nowakowski, and Rasmussen (1994) suggest that engaged learning tasks are challenging, authentic, and multidisciplinary. Such tasks are typically complex and involve sustained amounts of time... and are authentic. Quinn (1997) suggests that engagement in learning applications comes from two factors—interactivity and embeddedness, where the user perceives that they have some control over the system, and it is relevant and meaningful to them.

Beneficial

According to Csikszentmihalyi (1991), an optimal experience is so gratifying that “people are willing to do it for its own sake, with little concern for what they will get out of it” (p. 71). One might assume that what they are getting is some degree of pleasure. Jordan (2000) identifies pleasure as the ultimate quality of the user experience, and DeJean (2002) points out that pleasure is a complex concept. Apparently unpleasant aspects of the user experience, such as difficulty, challenge, and fatigue can all be pleasurable in certain contexts, for example, by generating feelings of achievement or superiority.

Bonapace (2002) adapts Maslow’s (1970) hierarchy of human needs to product use qualities. His pyramid begins with safety and well-being, moves up to functionality, and then usability which leads up to an apex of pleasure as the ultimate quality. Dunne (1999) explores the “aesthetics of use” and argues, “The most difficult challenge for designers of electronic objects now lies not in technical and semiotic functionality, where optimal levels of performance are already attainable, but in the realms of metaphysics, poetry and aesthetics, where little research has been carried out” (p. 7).

Liu (2003) describes qualities of “psychosomatic soundness,” referring to the extent that a product contributes to the “wholesomeness” or well-being of a person (from “harmful” to “healthful”) and the degree to which it is ethical (“bad/wrong” to “good/right”) (p. 1296). Knight (2004) too, argues for a reconsideration of the ethics of HCI design. The EDF uses the term benefit to include such concepts as ethics, psychosomatic soundness, pleasure, and self-actualisation.

The EDF, therefore, advocates designing for the four fundamental qualities of product use of accessibility, usability, engagability, and benefit. To do this it becomes necessary to widen the focus of research beyond cognitive and behavioural interaction, typical of usability, and HCI studies, to include a multi-dimensional approach to experience.

Dimensions of Experiencing

McDonagh-Philp and Lebbon (2000) suggest that emphasis must change “from hard functionality, to soft functionality” (p. 38). Rather than focusing on what a product does and how it does it, the focus is on less tangible aspects like emotional
associations, familiarity, aesthetics and taste. Fiore’s (2003) framework of experience considers physical, emotional, and intellectual aspects. In a similar vein, Norman (2004) describes emotional design in terms of its “visceral, behavioural, and reflective” elements (p. 63). He points out that these three levels of experience are not discrete but interact with each other. Spillers (2004) suggests, for example, that a new icon on a screen could arouse a state of curiosity or annoyance, producing a change in the user’s emotional state “which can either propel the user toward a feeling of satisfaction (success) or disappointment (failure)” (p. 2).

Jordan (2000) develops Tiger’s (1992) concept of pleasure, and describes four ways in which pleasure can be experienced: “Socio-Pleasure” arises from interaction with others or from a product that represents a social grouping; “Psycho-Pleasure” comes from the satisfaction felt when a task is successfully completed or from a product that makes a task more pleasurable. “Physio-Pleasure” is derived from the senses; and “Ideo-Pleasure” is derived from entities such as books, art and music or the values that a product embodies (p. 13-14).

The EDF uses Norman’s (2004) classification and adds a social dimension. The EDF, therefore, directs attention to the visceral, behavioural, reflective, and social dimensions of experience. Furthermore, it suggests that they be considered in the context of the use qualities. For example, considering accessibility in the context of each dimension may generate design goals such as:

- **Accessible/visceral**: legibility and visual clarity, text alternatives to audio content
- **Accessible/reflective**: limiting cognitive overload / clear, simple language use
- **Accessible/behavioural**: keyboard alternatives to using a mouse, shortcuts, voice input
- **Accessible/social**: culturally inclusive, secure, private, moderated

### Research Contexts

This section describes a set of key questions that can be asked throughout the design process to develop an understanding of the contexts of product use. The questions are derived from a number of models including Rothstein’s (2002) model consisting of the four As of “activity, artefacts, atmosphere and actors” (p. 3), and Ortony, Clore, and Collins (1998) cognitive model comprising “events, agents and objects (p. 63). The EDF advocates four key contexts: (1) who and why (users and stakeholders and their motivations); (2) what and how (content, tasks, task flow, actions, functionality); (3) when and where (situation, frequency, environment); and (4) with what (tools, knowledge, and skills).

### Who and Why

In order to be user centred it is necessary to identify who the users and stakeholders are and what motivates them to use a product. It is important to include everyone, however limited their involvement with a product might be. Users of a software system, for example, might include people that buy it, use it at home or at work, communicate through it, people who sell it, or sell on it, administrate it, repair it, install it or support it (e.g., Hackos & Redish, 1998).

When the focus of UCD goes beyond usability, it becomes necessary to collect data that pertain to the qualities and dimensions of the EDF. This might include: demographics (such as age, gender, ethnic origin, and culture); behaviour and skills (such as computer literacy, typing skills, embedded knowledge of a task or system); knowledge and experience (such as novice or domain expert, tacit knowledge); personal characteristics and motivations (such as personality, learning style, attitude, aspirations, values, beliefs, tastes, and preferences); and physical characteristics (such as dexterity, physical abilities, height).
What and How

This refers to the tasks or activities that will be supported, influenced, or affected by the product and how users carry out these tasks. Tasks are typically mapped from a behavioural perspective or cognitive dimension. Liddle (1996) suggests, “The most important component to design properly is... the user’s conceptual model. Everything else should be subordinated to making that model clear, obvious, and substantial” (p. 21). The EDF suggests that activities be considered in all dimensions. For example, an airhostess may be performing complex emotional tasks as well as checking in baggage (customer relations, anxiety reduction, risk assessment, etc.) (Hochschild, 1983).

When and Where

The role of context in understanding tasks was emphasised by Suchman’s (1987) notion of situated actions, that activity is conditional on the situation in which it takes place and is of an improvised rather than planned nature. What people say they are doing or how they do it, is an after-the-event rationalisation. Context should be considered in terms of all of the dimensions. For example, what is the user’s current frame of mind? What ideological factors will influence their experience? What aspects of the environment affect their visceral experience—are there loud distracting noises around or reflections on the screen? What emotional state is the user in? What other behaviours are they performing? What is the social context—is the product being used with friends to communicate, to play, to learn, or to work cooperatively?

With What

This refers to objects, artefacts, or tools that are being used or are influencing use (such as software, browsers, input devices, assistive technologies), and to knowledge, expertise, and skills that are used to carry out tasks. Considered in the context of qualities and dimensions, brainstorming, for example, might suggest that a haptic interface or 3D glasses (visceral) may improve engagability when viewing a virtual museum object. Conversely, users’ knowledge of existing interface conventions (reflective) may create expectations that reduce the usability of an innovative interface.

Methods and Tools

Reeves and Nass (2002) point out that people are rarely aware of their less rational motivations, so attempts to model what people are thinking or doing by asking them will not necessarily capture the reality of an experience. They advocate the use of methods from the social sciences to establish what people really think. The EDF suggests casting a wide net across many disciplines to find appropriate and useful methods.

Rather than prescribing a process or method, the EDF suggests that a range of tools and techniques can be employed provided they cover four basic purposes—exploration, empathy, communication, and evaluation. Furthermore, by applying these methods to the dimensions, qualities, and research perspectives, a better understanding of the user experience as a whole can be achieved.

Exploration

These methods are about discovery and can be drawn from demography, ethnography, market research, psychology, and HCI. They include surveys, interviews, questionnaires, focus groups, task analysis, field observation, user testing, affinity diagramming, laddering, and experience diaries. A key area of exploration is in understanding users’ mental models of a domain. This can be explored by, for example, in depth elicitation techniques and card sorts.

Contextual interviews are conducted during the activity or in the environment in which the product will be used. Users are able to refer
Design Methods for Experience Design

to artefacts, such as the documents, memos, and equipment that they normally use in their workflow, and indeed may be encouraged by the researcher to describe what they are doing. One of the most common methods of achieving this is to use the “think aloud protocol” (where users verbalise their actions). This has the advantage that the user is not relying on memory to describe his or her actions, and the researcher is able to note and probe omissions. There are some disadvantages however. The act of conscious reflection may change the way the task is performed and may create excessive cognitive load, or compete for the same cognitive channel as the task.

Both ethnography and ethnomethodology have been applied to eliciting contextual data. Ethnography is the study of a culture achieved by researchers immersing themselves in that culture in order to understand it, while ethnomethodology studies the ways in which participants give order to and make sense of their social worlds (Garfinkel, 1967). The focus of ethnomethodological studies is often at a very detailed level of interaction, including interaction between people and artefacts, technologies, and systems. For this reason it is a useful approach for the study of complex work situations, for example, air traffic or train control systems (Heath & Luff, 2000). The researcher may also use the artefacts produced by organisations, such as manuals and training materials; policies and procedures; and forms and documentation to enrich the detail of the observation. The rationale for applying these approaches to design is that the knowledge acquired will enable designers to work with, rather than against, users’ ways of understanding and making sense of the activities in which they are engaged.

Nevertheless, integrating these methodologies within the design process is not without its problems. The skills of trained ethnographers are often underestimated. Done properly, ethnographic methods involve sophisticated and skilful observation and recording techniques. The data may be far more detailed than the designer needs, and in a form that is difficult to interpret. Furthermore it can take many years to do a full ethnographic study, and for most software development projects, this amount of time is unrealistic. A simpler version may include shadowing target users for a short time, noting what they do and use, taking photographs, asking questions, and using techniques to elicit their values or emotional responses (Beyer & Holtzblatt, 1998).

Communicating

Design involves communication with a wide range of people, from users to software engineers. Design teams need to accommodate different viewpoints and share a common language. Curtis (2002) emphasises the importance of actively listening to a client and finding out the story behind a product. Hammer and Reymen (2004) stress the importance of designers expressing their emotional as well as rational reflections on design decisions. Communication methods serve to clarify and share the goals of stakeholders, the exploratory research data, design requirements, and ideas to a multi-disciplinary team who may not have a common vocabulary. It is important to ensure good communication throughout the process to ensure the product itself communicates the design goals effectively. Methods include story telling; user profiles and personas; use cases or task scenarios; scenario-based design; mood boards; written briefs and specifications; storyboarding; and prototypes.

User profiles are generated from demographic data and lifestyle surveys. They can include textual and visual descriptions of key user groups. They are used to think through design solutions and for recruiting users for research. Mood boards are normally collages of photographic information that aim to generate a visual “personality” for the product or service. Mood boards can be created by designers or users or be the result of collaboration between the two. Mood boards are useful because they work at a nonverbal level where
people may otherwise have difficulty expressing their wants and needs. Storyboards are time-based often with a narrative aspect. Storyboards can be sketches or low-fidelity screen shots of a user’s interaction. Prototypes range from paper sketches to working interactive replicas. Information architecture can be communicated through formalised diagrams and charts or simple tree structures and hierarchies.

Empathy

These methods represent an approach aimed at gaining a deeper understanding and empathy for users. They include focus groups, diaries, workshops, participatory design, and immersion. Diaries can be used to record users’ interaction with a product over time while workshops and participatory design involve users in the development team either directly or through a user advocate that champions their perspective. Participant observation, or “eat your own dog food,” involves taking part in the activity or culture being observed, where the designer becomes a user. Molotch (2003) describes a method used by Ford designers in which they test products “dressed in what they call a ‘third age’ suit, with glasses and gloves, to simulate having the body and eyesight of a 70-year old” (p. 49).

Crossley (2004) describes a technique used to help designers develop an awareness of the target audience for male grooming products. It involved:

*rapidly immersing the design team into the lives, hearts and minds of people in a short space of time. The challenge for this project was to get young men inspired to tell us their own stories and express their emotions about a mundane functional activity*”… “Character modelling [was used] … where the team and sometimes the user has a kit with questions, cameras and collages, [that enabled them] to frame and understand the lifestyle of the person they are creating for.” (pp. 38-39)

Personas are used to develop a shared vision of end users among development teams. They can be textual, visual, animated, or acted. One of the most important functions of personas is to get teams to think differently about people, as Cooper (1999) notes:

A fully realized, thoroughly defined user persona is a powerful tool. Until the user is precisely defined, the programmer can always imagine that he is the user. A completely pronounced user persona is key to the suppression of any tendency for the developer to usurp or distort the user persona’s role. Long before a single line of code is written, a well-defined user persona becomes a remarkably effective tool for interaction design. (pp. 128-129)

Role-play is often used to encourage designers to empathise with users. Dramatic techniques can also help teams get into the minds of users and their values. Carmichael, Newell, Morgan, Dickinson, and Mival (2005) describe how the UTOPIA project improved designers’ understanding of requirements. Using professional actors the project developed video scenarios of elderly people using technology. This was then shown to design teams to encourage them to design for others rather than themselves.

Speculation

In addition to understanding users’ wants and needs, designers also need to speculate about new solutions and future trends. The Sony Walkman, for example, introduced an entirely novel mode of behaviour that no users had asked for. The decision to add text messaging to mobile phones was based on a speculation of how that functionality might be needed and by whom. The success of text messaging, however, was based on its uptake by an entirely different user group with its own needs and method of use. Designers may need to predict how users will adopt and adapt to a new product.
Design Methods for Experience Design

Here the solution is not tied to a particular technology or need but to reconceiving it. Good design requires up-to-date knowledge of what is possible and the ability to see beyond the obvious. There are a number of methods that achieve this. Jones (1990) sees speculation as “divergence, transformation and convergence” (p. 64-68) and suggests methods such as brainstorming (search for alternatives) and synergetics (search for alternatives by analogy).

Rosson and Carroll (2002) describe scenario-based design in which scenarios are deployed throughout the design process to speculate the future. Scenarios can be used to challenge existing practices and encourage users and designers to think beyond the confines of the current situation. Dunne (1999) describes the use of scenarios to communicate design ideas and to stimulate thinking beyond the preexistent reality. He suggests that they can “push the viewer towards a more complex, emotional or revolutionary understanding of the problems posed” (p. 75). By testing design ideas rather than prototypes, the user’s attention is shifted from the “aesthetics of construction” to the “aesthetics of use” (p. 73).

Speculation and innovation are, in part, about predicting the future, and a number of methods have been developed for this. The UK Cabinet Office published a Futurist’s toolkit (UK Cabinet Office, 2001) describing six key methodologies for futures work, including quantitative and qualitative trend analyses, the Delphi survey method, scenario methods, wildcards, and future workshops. Cayol and Bonhoure (2004) describe a methodology which used sociological studies predicting the evolution of French people for the year 2025, to identify and evaluate future product concepts.

De Bono (1995) uses lateral thinking to generate different scenarios and ways of thinking about problems. De Bono’s “Six Thinking Hats” (pp. 78-79) is a method for creative thinking but is also useful for developing empathetic intelligence. This method involves six team members role-playing different aspects of the design process. Thus the white hat is neutral and reflects back opinions and ideas, whereas the black hat is judgemental, cautionary and avoids mistakes. Speculative methods are important because design teams need to be able to see beyond user requirements and consider latent needs and potential opportunities.

Evaluation

Evaluation methods include auditing, standards compliance, and user testing. Evaluating may also use similar methods to exploration, with a shift in emphasis from discovery to checking outcomes against intentions. Does the product meet the design goals and/or the user expectations? Evaluation can be formative, conducted during the development of a product, or summative, conducted when a product is complete and is being used. Summative testing of an earlier version or a similar product can be useful to identify design goals, while summative testing of the product at the end of its design lifecycle is usually done for auditing and verification purposes. Feedback at this stage is of little use to the designer, the deadline has passed and the money is spent. Clearly formative testing is most helpful to a designer/developer. Gould and Lewis (1985) stress the importance of empirically testing design iterations throughout the design process. Evaluative tools such as heuristics are often used, although evidence suggests that they are no substitute for testing real users (e.g., Lee, Whalen, McEwen, & Latremouille, 1984). The EDF broadens the test and evaluative criteria from the traditional focus on cognitive and behavioural measures. Bonapace (2002) describes a method aimed at tapping into the four pleasures described by Jordan (2000), called the Sensorial Quality Assessment Method (SEQUAM) applied to the design of physical products in car manufacturing. User testing can combine empirical methods of behavioural observation with techniques such as co-discovery, think aloud and empathic interviewing, to tap into
the subjective aspects of experience.

Establishing evaluation criteria at the begin-
ning of a design process helps to focus the evalua-
tion process from the beginning, although it is wise
to allow some freedom for the evolution of design
goals through iteration and to allow evaluative
concerns to emerge (Hall 2005). The EDF can be
used to generate evaluative criteria for qualities
in each dimension and context of use.

**APPLYING THE EXPERIENCE DESIGN FRAMEWORK**

The authors have used the EDF to adapt and focus
methods for requirements research, brief develop-
ment, ideation, and testing and have developed
a range of services and training based on it. The
EDF has been particularly useful in generating
design goals, aiding decision making, and devel-
op ing user-testing scenarios. Some examples of
applications follow.

**Visioning Workshops**

Visioning workshops usually take place at the
beginning of the design process, preferably before
the brief is finalised. The workshop is structured
around the experience design framework and ful-
fil s a number of functions. Techniques are adapted
to improve communication; to build literacy and
a common language to describe the medium; and
to build an empathic understanding of users and
other contexts of use. Individual and group activi-
ties are facilitated by a researcher and recorded
by a scribe. Activities include the following:

- Participants identify their vision of the
  project goals and their personal objectives,
  roles, and stories.
- Participants share their personal preferences
  and tastes by discussing examples of the
  product type or medium from visceral, be-
  havioural, reflective, and social perspectives,
  and in so doing, build up a shared language
  for product qualities.
- Participants discuss the nature of the design
  problem from different perspectives and
  use speculative techniques to generate new
  ideas.
- Participants identify audience and stakehold-
  ers; then develop personas and scenarios
  based on different contexts of use.
- Participants share desired product qualities,
  functionality, and content from the perspec-
  tive of the stakeholders identified.
- Participants identify and prioritise product
goals and develop evaluative criteria.

By the end of the workshop, participants have
prepared the foundations of a creative brief, have
started working together as a team, and have
formed a common language and shared under-
standing of the project goals.

**Contextual Interviews**

Contextual interviews take place prior to detailed
requirements specifications and may follow a
visioning workshop. Firstly, stakeholders are
identified and a representative sample recruited.
The aim is to survey a large sample and to it-
teratively develop knowledge about the design
problem. In this context, as many as 50 users may
be involved and the focus is to gain as full a set
of requirements as is possible in a short space of
time. The interviews are semi-structured over
approximately 30 minutes and are conducted
within the context of use. Their exact format is
dependent on whether the product is a new one or
a refinement of an existing one. In the former case,
the researcher works with low-fidelity prototypes
and in the latter case with the existing product.
Activities include the following:

- Stakeholders are asked to provide docu-
  ments, processes, and artefacts involved in
  the tasks.
Interviewees are asked to complete a persona template with details about themselves, their interests, and their lives.

- Interviewees are asked to identify critical tasks, events, and work-arounds with the existing product.
- Interviewees identify relationships with other users/stakeholders in their use of the product, and what other tools or products they use in association with the tasks.
- Interviewees are asked to describe key tasks with the product and/or walk through a task. The interviewer elicits details of any prior knowledge, expertise, or skills being applied to the tasks and probes for emotional responses to aspects of the activity.
- Interviewees are asked to describe how the product fits in with their daily life.

The results of interviews inform the production of anonymous personas and use scenarios, which are used to communicate the requirements to the development team and build their empathy with the users.

**Conceptual Design Workshops**

Conceptual design workshops involve development teams rethinking the design problem and considering potential solutions. The aim is to generate a number of alternative design concepts. These are then evaluated and then “worked up” for initial user testing or participatory prototyping (see what follows). Workshop members usually include members of the development team plus representatives of key stakeholders. The workshops are structured around the EDF and activities include the following:

- Participants reconceptualise the design problem in terms of the EDF’s contexts.
- Participants brainstorm and develop a number of design concepts.
- The concepts are discussed and similar solutions are merged together and evaluated against the EDF’s qualities.
- The process is repeated until a number of distinctly different and viable concepts have been generated and can be tested on users.

**Participatory Prototyping**

Participatory prototyping combines the skills of the development team with user feedback. Prototypes are developed of content structures, interaction flow, and layouts. Initial prototypes are developed and users are asked to critique or adapt the prototype with specific reference to the qualities of the EDF and the dimensions of experience. Designers interpret this feedback and develop further prototypes, with the focus on interaction and structure, and later on look and feel issues. Activities include the following:

- Users are asked to card sort content or to map out their expectations of content domains and structures.
- Users are asked to “walk through” prototypes in order to carry out their key tasks, using the think aloud method.
- Responses to the organisation of the interface and the terminology used are elicited.
- Users perform tasks with the prototype and are asked to speculate on improvements, applications, or additional features.
- Where trade-off or multiple interfaces exists users sort the prototypes on the basis of their preference.

By the end of the process a complete low-fidelity prototype has been developed that has been iterated around the qualities of the EDF.

**Audience Reception Workshops**

Audience workshops review the final prototype design. Users are recruited to represent the key
stakeholder groups. The prototype then undergoes a group critique that tests the solution against the initial requirements and evaluative criteria gathered by the visioning workshop and contextual interviews. As well as ensuring that the prototype is suitable the workshops gauge barriers and opportunities to take up and adoption of a new product or design. In addition, it provides the development team with a rationale and evidence of the suitability of the final design solution. Activities include the following:

- Group walk-throughs of the prototype
- Identification of conflicts and trade-offs
- Comparison of look and feel prototypes
- Quantitative research methods and user attitude measurement

**Post Implementation Research**

Post implementation research reviews the application after launch. Unlike traditional usability that focuses on requirements and development, this research is necessary to monitor changing user needs throughout the product’s lifecycle. A user cohort is recruited and is asked to provide regular feedback based on the EDF. As well as ensuring that maintenance and new features are accepted by users this research is important to identify new products and user needs. Activities include the following:

- User diaries
- Online discussion groups and surveys
- Focus groups and ongoing user testing

**CONCLUSIONS AND THE FUTURE OF WEB EXPERIENCES**

The EDF was created in response to the needs of clients and has generated research, which has fed back into the design of services. The EDF has been applied to a number of internal and external products and has been refined through practice. The EDF is meant to provoke discussion, raise questions, challenge assumptions, and generate alternatives.

Every design problem is different and so it is necessary to deploy a range of research methods to support the work of the digital media designer. Nevertheless, these methods should be focused around the key issues for UCD, which is to understand users, the tasks they undertake, and the contexts in which they function. They provide a rich understanding of users from which the creative designer can create usable and desirable products. The EDF helps teams focus requirements research and can be used in a workshop environment with a range of stakeholders and users. The EDF can be used as a brainstorming tool that aims to map out the requirement and the process, and possible solutions from the team and stakeholders.

If methods are focused around qualities, dimensions, and contexts of experience, they provide a richer understanding of users from which the designer can create usable and desirable products. The EDF provides a reminder of the complexity of the user experience and can be used throughout the design lifecycle.

Chapter 2.6
Integrating Usability, Semiotic, and Software Engineering into a Method for Evaluating User Interfaces

Kenia Sousa

Albert Schilling
University of Fortaleza, Brazil

Elizabeth Furtado
University of Fortaleza, Brazil

Abstract
We present artifacts and techniques used for user interface (UI) design and evaluation, performed by professionals from the human-computer interaction (HCI) area of study, covering usability engineering and semiotic engineering, which can assist software engineering (SE) to perform usability tests starting earlier in the process. Tests of various interaction alternatives, produced from these artifacts, are useful to verify if these alternatives are in accordance with users’ preferences and constraints, and usability patterns, and can enhance the probability of achieving a more usable and reliable product.

Introduction
In a software development process (SDP), it is crucial for developers, customers, and users to interact in order to specify, generate, and evaluate the software. From software specification to its delivery, various kinds of tests must be performed, involving aspects such as: functionality, portability, performance, and usability. This work focuses on the context of usability, communicability, and functionality tests (e.g., appropriateness of a chosen interface design alternative to user preferences, consistency to a visual pattern, efficient execution of interactive tasks on interface objects, etc.).
Through our researches on tests in HCI and SE, and through our experiments on their integration in a SDP, we verified that HCI concepts facilitate the UI evaluation work performed by the test team of an interactive system under development. More specifically, by means of UI generation based on HCI models (e.g., task model), it is possible to evaluate the UI earlier (e.g., its functionality), independent of having the entire noninteractive specification ready. Prototypes, for instance, can represent UI design alternatives that may be tested early by HCI experts to verify if they are in accordance with user preferences, usability patterns, and so on.

This work presents a SDP to design and evaluate UIs, based on the integration of concepts, models, and activities of usability, semiotic, and software engineering.

This chapter is structured as follows: The “User-Interface Evaluation” section shows the contribution of each engineering area to UI evaluation; “The Process” section describes the UI design process; “The Evaluation Strategy” section describes the UI evaluation process, showing which concepts are used to perform tests and when they are performed; the “Case Study” section describes the case study in which we designed and evaluated UIs for the Brazilian System for the Digital Television (SBTVD); and, finally, the “Findings and Future Works” section describes findings and future works, and the “Conclusion” section concludes this work.

**USER-INTERFACE EVALUATION**

In this section, we present concepts and evaluation techniques from usability engineering, software engineering, and semiotic engineering.

**Usability Engineering**

Usability engineering is a set of activities that ideally take place throughout the lifecycle of the product, with significant activity at the early stages even before the UI has been designed. The need to have multiple usability engineering stages supplementing each other was recognized early in the field, though not always followed in development projects (Gould & Lewis, 1985).

In usability engineering, techniques and methods are defined aiming to assure a high usability level of the interactive UIs. Among them, we emphasize the application of ergonomic criteria in the UI design. Verification of these criteria in designed UIs is called heuristic evaluation, performed by usability experts without user participation. Evaluators examine the IS searching for problems that violate general principles of good UI design, diagnosing problems, obstacles or barriers that users will probably encounter during their interaction. In addition, methods to capture usability requirements attend to user preferences, restrictions, and use-context. A usability requirement can be derived from an interaction restriction; such as if part of the system needs to be implemented for palm-top devices.

The evaluation approaches from usability engineering suggests a structured sequence of evaluations based on “usability inspections methods” and on “usability tests”.

Some inspection methods are: (1) heuristic evaluation, verification of usability heuristics (Nielsen, 1993); (2) review of guidelines, verification if the UI is according to a list of usability guidelines (Baranauskas & Rocha, 2003); (3) consistency inspection, verification of the consistency among the UIs related to terminology, color, layout, input and output format, and so on; and (4) cognitive walkthrough, simulation of the user “walking” through the UI to execute typical tasks.

Some usability test methods are: (1) thinking out loud, we request the user to verbalize everything he or she thinks while using the system, and we expect that their thoughts demonstrate how the user interprets each UI item (Lewis, 1982); and (2) performance measures, quantification of some evaluated items to make future comparisons.
Software Engineering

Software engineering is composed of technologies and practices that are used in the development of software products, enhancing software productivity and quality, by providing a more systematic and controlled SDP (Sommerville, 2001).

In software engineering, there are various types of tests to be performed in each test stage, such as: usability tests to ensure that access and navigation through functionalities are appropriate for users; UI tests, to ensure a good functionality of the UI components and verify conformity to corporate patterns; and functionality tests, which are responsible for verifying if the generated software achieves all the proposed functionalities according to the customer’s requests. Test cases (Myers, 2004) are normally generated and comprise procedures to be followed in test activities in order to deal with all possible situations when using the software, including basic flows, as well as error treatment and invalid data verification.

According to Pressman (1995), the main goal of test cases is to derive a set of tests that will probably reveal errors in the software. To achieve this goal, software engineering basically proposes two test categories: white-box and black-box tests.

For Pressman (1995), the white-box test must verify the internal part of the product, tests can be performed to guarantee that the components are integrated, and the internal operation achieves the performance level as specified in the requirements.

Functional tests, or black box tests, represent a test approach in which tests are derived from specifications of the system. In this kind of test, the evaluator is concerned with the functionality, not with the software implementation (Sommerville, 2001).

In these two test categories, software engineering defines four main types of tests: unit tests that are generally white-box tests; acceptance and regression tests that are usually black-box tests, and integration tests that blend this two categories.

Semiotic Engineering

Semiotic engineering is an HCI theory that emphasizes aspects related to the metacommunication designer user(s) via user-system communication, which passes through the UIs of interactive applications. The system is considered to be the “deputy” or a representative of the system designer (Souza, Barbosa, & Silva, 2001). The content of messages is the application usability model. Its expression is formed by the set of all interaction messages sent through the UI during the interaction process. The user plays a double role: interacting with the system and interpreting messages sent by the designer.

Semiotic engineering is essentially involved in test procedures with final users (empiric evaluation), aiming at system communicability analysis — based on qualitative evaluation, in which there are four phases: test preparation; labeling; interpretation, and formatting — and elaboration of the semiotic profile of the application to be evaluated. The techniques used in these phases are: system-user observations, questionnaires, (somative-evaluation) inspections, interviews, filming, and so on.

Semiotic engineering is essentially present in tests with final users (e.g., empiric evaluation), aiming at analyzing the system communicability. A UI has a good level of communicability when it is able to successfully transmit the designer message to the user, allowing him or her to understand the system goal, the advantages of using it, how it works, and the basic UI interaction principles.

Evaluation

After studying about evaluation techniques, artifacts and approaches from software, usability, and semiotic engineering we are able to conclude that an evaluation process can be seen under various perspectives.

Concerning software engineering, we noticed the importance of software quality concerning
functionality, performance, portability, and other nonfunctional requirements. Its artifacts and techniques include the evaluation of these aspects in an objective manner.

Usability engineering focuses in providing more ease of use, ease of learning, and efficiency to interactive systems.

Semiotic engineering includes procedures that allow the evaluation of the quality of the interactivity of systems by observing the communication through messages of the user to the system.

Based on these perspectives, we believe that an approach for UI evaluation of interactive systems that integrates these approaches is able to guarantee a system with quality concerning functionality, usability, and interactivity, derived from software, usability, and semiotic engineering, respectively.

Next, we will describe a lightweight development process for interactive systems, called UPi (Sousa & Furtado, 2004), which integrates HCI and SE activities, artifacts, and professionals.

THE PROCESS

UPi can serve as a guide, providing useful steps and artifacts that can be tailored and customized when organizations intend to develop usable interactive systems. One of the best advantages of UPi is the idea to focus on activities, artifacts and guidelines that add value to the UI generation. With this approach, it can be integrated with any other process and inherit activities that are vital to the entire process, but that are better defined and solidified in other processes. For instance, project management, configuration and change management, implementation, and deployment activities are very well detailed in the RUP (Kruchten, Ahlqvist, & Bylund, 2001). Besides the RUP, UPi can also be applied in conjunction with ISO 13407 (ISO 13407, 1999), which already has other activities defined and validated, such as project planning, testing, and so on.

UPi is composed of activities that aim at designing UIs. These activities are based on RUP activities, but they follow different guidelines that take into consideration usability aspects.

In this work, we are integrating UPi with UPi-Test (to be presented in the next section) in order to guide professionals that are developing interactive systems to evaluate them throughout the entire development process.

Phase I: Inception

The main goal in this phase is to elicit requirements from users in order to develop an interactive system that best suits their needs through the execution of some activities (presented as follows). These requirements are documented through certain artifacts: use-case models, task models, usability requirements, and paper sketches.

*Use-case models* represent a well-established manner to define the system functionality, while *task models* can be used to detail use cases by breaking them down into tasks. *Usability requirements* represent users’ preferences or constraints that can be part of a usable interactive system. *Paper sketches* focus on the interaction, UI components, and on the overall system structure, keeping the style guide secondary, without being too abstract.

The purpose of the *Elicit Stakeholder Needs* activity is to understand users, their personal characteristics, and information on the environment where they are located that have a direct influence on the system definition, and to collect special nonfunctional requirements that the system must fulfill, such as performance, cost, and device requests.

The purpose of the *Find Actors and Use Cases* and *Structure the Use-case Model* activities is to define the actors (users or other systems) that will interact with the system and the functionality of the system that directly attend to users’ needs and support the execution of their work productively.
The purpose of the Detail a Use Case activity is to describe the use case’s tasks using the task model, to describe any usability requirements related to the use case, to define the system navigation based on the task model hierarchical structure, and to create paper sketches.

The purpose of the Review Requirements activity is to verify, with usability experts, if the paper sketches are in accordance to the task model and validate, with users, if the requirements are in conformance with their needs by showing them the elaborated paper sketches.

**Phase II: Elaboration**

The main goal in this phase is to transform the requirements in a representation that can be understood by UI designers and programmers. These representations are provided by the following artifacts: system architecture, UI Definition Plan, and drawing prototypes.

System Architecture is composed of smaller components that represent the main functionality of the entire system. The UI Definition Plan is a new artifact that aims to define which visual objects should be part of the UI. Drawing prototypes produce an accurate image of the system and they are useful to demonstrate patterns and style guides.

The purpose of the Define and Refine the Architecture activity is to (re)design the classes that represent the data that are handled by users while performing certain tasks.

The purpose of the Define UI Plan activity is to define which visual objects and which usability patterns can be part of the UI according to the nonfunctional requirements defined in the Elicit Stakeholder Needs activity.

The purpose of the UI Prototyping activity is to design a UI prototype in drawings following the description specified in the task models, in the UI definition plan and in the system architecture.

The purpose of the Evaluate Prototype activity is to verify if the UI prototypes are in accordance to usability principles and to validate with users if the UI prototypes are in conformance with their needs.

**Phase III: Construction**

The main goal of this phase is to implement and verify the accuracy of the components implemented and of the UI designed.

The purpose of the Implement Components activity is to develop the classes previously designed and implement the UI prototyped.

The purpose of the Evaluate the Version of the System activity is to verify if the functionality of the interactive system is in accordance with users’ requirements.

**Phase IV: Transition**

The main goal of this phase is to deliver to the customer a system with high level of quality and usability.

The purpose of the Deploy the System activity is to make the system available for the customer.

The purpose of the Evaluate the System activity is to validate with users (by using the system in the deployment site) if the system conforms with their view of the system.

All of these phases are supported by processes concerning configuration and change management and project management, such as the RUP. This support is provided for the Manage Change Requests activity, which aims at evaluating the impact of change requests, deciding if they are to be included in the current iteration, and, if they are accepted, manage the changes in the appropriate artifacts.

Concerning the evaluation activities performed in each phase, they will be more thoroughly explained in the next section.

THE EVALUATION STRATEGY

The unified process for evaluating interactive systems “UPi-Test” (Schilling et al., 2005) has the same phases as the RUP (inception, elaboration, construction, and transition) (Kruchten, Ahlqvist, & Bylund, 2001). This process is based on the Unified Process for Interactive Systems, called UPi (Sousa & Furtado, 2004) and follows the approach to design UI prototypes dependent on the device (Coyette, Faulkner, Kolp, Limbourg, & Vanderdonckt, 2004).

Each phase is directly related to a specific area. This way, usability engineering supports the verification and validation in the inception and elaboration phases, software engineering supports verification in the construction phase, and semiotic engineering supports validation in the transition phase.

Figure 1 illustrates these four phases in the UPi-Test, each one with its flow of activities, artifacts, and techniques.

UPi-Test includes the verification and validation of usability and functionality of interactive systems UIs. Nonfunctional requirements are not in the scope of this work, such as aspects related to database (e.g., connection, integrity, etc.), security, and architecture. These aspects can be supported in future versions of this process.

Phase I: Inception

The inception phase is important in guaranteeing that the following phases achieve results to attend to users’ and customers’ usability goals. This phase has the constant participation of users in order to understand their requests, which are verified and validated according to usability engineering to allow the development of these requests. The description of the activities and artifacts in this phase is presented as follows.

Talk with Users and/or Customers

This activity consists of the first contact with users or customers, in which system analysts understand their profiles, objectives, and the scenario where they are included. In this activity, it is necessary to use a technique to elicit requirements.

We propose an initial informal talk in order to better understand users’ environment. Then, we suggest the performance of interviews, with the use of a questionnaire that aids in the identification of users and/or customers and their intended goals, preferences, and possible constraints.

Obtain Users’ and Customers’ Preferences and Constraints

In this activity, system analysts aim at eliciting users’ and customers’ preferences and constraints in order to design UIs that attend their needs and also to help usability experts during evaluation and to help UI designers during prototyping. Some examples of preferences are: design colors, font styles, navigation schemes. Some examples of constraints are: technology constraints, such as platform, device, and so on.

Consider HCI Models and Use Cases

Use cases represent an artifact from software engineering that identifies the functionality of interactive systems; users’ interactions, expressed through users’ tasks; and the system’s responses to perform these interactions (system’s tasks).

Task models detail a use case or a group of related use cases by specifying users’ tasks and system’s tasks. It is useful to support UI designers in the elaboration of prototypes because it is easy to identify the necessary views and objects in the prototype from the task model hierarchical structure.
Figure 1. Evaluation process of UIs
Analyze Existing Systems

In this moment, it is important to analyze existing systems. This involves a comparative study of similar systems. These systems can be used as a reference in order for system analysts to propose new functionality or to choose design patterns, which are all useful for the design of UI prototypes.

Consider Paper Sketches

After talking with users and customers, the UI designer designs paper sketches. This prototype is verified and validated, as presented in the next activity.

Verify with Expert

This activity consists of the verification of paper sketches by the usability expert. The expert is concerned with verifying if users’ goals, in terms of functionality, were included in the prototype, as well as if usability principles were used.

We propose that experts use the heuristic evaluation approach (Nielsen, 1993) as an inspection method. The usability heuristics will guide the usability expert in the process of verifying UIs’ quality of use. We also suggest the use of the task model to verify if all the specified functionality was designed in the prototype.

When the expert notices that a functional requirement or any usability principle is missing, change requests can be made, which leads to changes in the models and new proposals of prototypes.

Validate with Users and Customers

After the verification with the expert, we propose a validation with users and customers so they can approve the generated artifacts. If the prototypes do not attend users’ needs, change requests can be made, which leads to changes in the models (if new functionality is requested) and new proposals of prototypes (if changes in the navigation are requested). This process is repeated until the generated prototype attends users’ preferences and needs.

This activity early in the process provides flexibility for users and customers to evaluate the evolution of the system, therefore, designers and users feel more confident with the UI design.

After the conclusion of the inception phase, the resulting artifacts are verified and validated as paper sketches.

Phase II: Elaboration

The elaboration phase is concerned with designing and evaluating drawing prototypes. In this phase, we use verification and validation techniques, such as heuristic evaluation and validations with users. After this phase, the resulting artifacts are drawing prototypes validated according to usability requirements and patterns. The description of the activities and artifacts in this phase is presented as follows.

Use Design Patterns

In order to guarantee the quality of the product and efficiency of the project, we suggest the use of design patterns for graphical UIs. These patterns will guarantee that we elaborate and develop UIs following already verified and validated parameters, which can be incremented by the reports generated in the end of the transition phase.

Consider Drawing Prototypes

UI designers are responsible for designing drawing prototypes based on paper sketches previously validated, and on usability patterns. These prototypes are verified and validated by the following two activities.
Verify with Expert

This activity consists of verifying the usability of drawing prototypes by experts. We propose that experts use the heuristic evaluation approach (Nielsen, 1993) as an inspection method to verify whether or not certain usability principles are present in the prototype.

When the expert notices that any usability principle is missing, change requests can be made, which leads to new proposals of prototypes. At this moment, it is not necessary to make changes in the models because this approach evaluates the quality of use, not functionality aspects, which were evaluated in the previous phase.

Validate with Users and Customers

After verification with the expert, a validation is proposed to users and customers so they can approve the generated prototypes. At this moment, users and customers evaluate the used usability patterns and the style guide. This process is repeated until the generated prototype attends users’ preferences and constraints. If the prototypes do not attend users’ needs, change requests can be made, which leads to new proposals of prototypes.

After the conclusion of the elaboration phase, the resulting artifacts are verified and validated drawing prototypes, which support development, tests, and deployment activities.

Phase III: Construction

In this phase, the UI is developed and the application is integrated with it. Considering software engineering, we propose functionality tests of an executable prototype (i.e., a product with some functionality) or the final product (i.e., a product with all the functionality), using functional test cases.

The activities and artifacts in this phase are presented as follows.

Implement and Integrate

These activities consist of developing the UI and integrating it with the application. The integrated product, either a prototype or the final system, can be useful for evaluating the navigation, interactivity, and functionality aspects.

Elaborate Test Cases

Test cases can be elaborated starting in the inception phase, using paper sketches, they can then be updated in the elaboration phase, using drawing prototypes, and finished in this activity. This artifact focuses on the system functionality, not on nonfunctional aspects.

The technique used to define test cases includes the following topics: association to a use case, specification of the item to be tested, preconditions to execute before testing, identification of valid and invalid inputs, and the expected outputs. The actual outputs are compared with the expected outputs described in the test cases and this comparison is used as validation of the use case.

Verify with Expert

This activity consists of the verification of the functionality of the product by usability experts and developers. Examples of aspects that are verified are: consistency of the outputs, navigation, existence of error messages, results after clicking on objects, as well as other aspects identified in the test cases.

After this verification, developers and experts can generate change requests to correct the errors; which leads to the repetition of the implementation and integration activities.

After the conclusion of the construction phase, the resulting artifact is the integrated product, which is tested with consideration to usability aspects in the transition phase.
**Phase IV: Transition**

This phase comprehends, in general terms, the preparation of the test environment, which can be a test laboratory or the environment where the system is used. With consideration to semiotic engineering, we use some validation techniques and artifacts. The description of the activities and artifacts in this phase is presented as follows.

**Prepare the Environment**

To prepare the environment, we suggest the installation of the system, software for capturing the system’s use, and equipment, such as video cameras and necessary hardware devices. We also suggest the creation of questionnaires and checklists.

The test laboratory must be similar to the real user environment — with consideration to physical structure, climate, sound aspects, and equipment — in order to allow users to live the same conditions of the real environment. There should be a room where the test takes place and another one for observation.

**Install the Product**

In this activity, the product is installed, either a partial version or the final version of the system, in order to allow users to use the system in their real environment. This installation allows the tests to be performed.

**Usability Tests “with Users”**

This evaluation is performed with users. In it, evaluation techniques, proposed by semiotic engineering, are used, such as: recording, observation, questionnaires, and so on.

Before starting the tests, the usability expert talks with the user in order to: clarify that the system is under evaluation, not him/her; present the scenario used for the test; and make the user feel comfortable; which are aspects that influence the final results.

Observers that are in the observation room should fill out the questionnaires and checklists.

This activity can be divided in two moments, the first one, when the user interacts with the system to perform a task of his/her own interest; the second one, when the expert requires the user to perform a specific task.

In this activity, navigability, interactivity, and acceptability will be evaluated.

**Use Observations/Checklist/Questionnaires**

Observations, questionnaires, and checklists are artifacts and techniques proposed by the semiotic engineering in order to verify the user-system interactivity and communicability. Experts and observers will use these artifacts during the tests, which result in the definition of the quality of the interactive system. These results can lead to change requests for developers to correct the detected mistakes.

Users’ comments and the actual execution of the tests will be recorded to help in the analysis of the results of the questionnaires and of users’ observations.

**Make Corrections**

In this activity, developers make corrections proposed by experts after the tests. After the changes are made, users validate the product.

**Deliver the Evaluated Product**

As a result of the process, we have the results of evaluations, which are useful for future versions; and we also have a verified and evaluated product according to a set of techniques proposed by usability, software, and semiotic engineering.

If the product is a final version of the system,
it is ready to be delivered for use. If it is a partial version (e.g., executable prototype), the professionals need to perform the activities in the construction phase, then in the transition phase, until the product reaches its final version.

Elaborate Reports

The results obtained will be used as a basis for the elaboration of evaluation reports, which propose adaptations in the used patterns and in the creation of new patterns that can be used in future iterations.

CASE STUDY

In this chapter, we describe the case study of this research work, which is concerned with the evaluation of UIs for the SBTVD project, focusing on the applications: electronic portal, insertion of texts, and help.

Introduction

The digital TV represents digital and social inclusion for a great part of the Brazilian population, especially for people less privileged, who do not have access to computers, and therefore, cannot access the Internet.

The SBTVD must be adapted to the socioeconomic conditions of the country, as well as allow the use of conventional TV sets already in large use in the country in order to decrease risks and costs for the society.

The digital TV creates various possibilities of interaction between the TV and the user, such as: exchange of text or voice messages, virtual chats, searches for a favorite show, access to information about the government, and so on. These possibilities are different from the characteristics of the conventional TV, in which the user plays a passive role.

In the following section, we describe the performance of the activities proposed by UPi and UPi-Test. It is important to point out that the SBTVD is still under development. That is the reason why we cannot demonstrate all the activities of the process.

Phase I: Inception

Talk with Users and/or Customers

This activity was difficult to perform in this project because there is an almost unlimited number of users and/or customers. Fortunately, there were specific and clear specifications, established by the Brazilian government. Such specifications were used as requests from users and customers.

To define the scope of the application under our responsibility (access portal), we had meetings with representatives of the government and with other institutions that are participating in the project. These meetings were supported with brainstorming and the resulting decisions were analyzed and were shared with all the institutions through e-mails and discussion lists.

After these meetings, we decided that the portal will consist of a main application that allows the access to all other applications in the SBTVD, which can be: electronic mail, electronic commerce, EPG, help, electronic government, and so on.

Obtain Users’ and Customers’ Preferences and Constraints

The SBTVD project is concerned with various users’ profiles, including the ones who are and those who are not used to technology, but not including the ones with any kind of disabilities.

In order to identify their possible preferences and constraints, we studied existing systems; we had many meetings and workshops. The opinions of all the participants in the project were taken into consideration because we can also be considered to be potential users.
Our main goal in the usability workshops was to choose the best usability pattern for each requirement based on the evaluation of positive and negative aspects of each proposed usability pattern, as specified in the UPi activity define UI plan.

These proposed usability patterns were selected from a list, such as the one available in Welie (2005), which are organized in the following format: problem to be solved, solution, context in which it can be used, and graphical illustration.

For the participants to evaluate the usability patterns, we provided a set of guidelines. After they read the guidelines, each group evaluated the positive and negative aspects of each usability pattern suggested for the requirement. Then, the participants discussed and reached the final decision as to what was the best usability pattern for the requirement under discussion.

The personalization group considered the guidelines as they evaluated the positive and negative implications of each usability pattern, aiming at achieving Nielsen’s usability goals. For demonstration purposes, we focus on presenting the personalization of colors.

As a result of the evaluation, the personalization group decided to use color templates because of the greater impact of positive implications over the negative ones. The result of this work was the generation of a document associating usability patterns with their positive and negative implications. For instance, the selected pattern with more positive implications was “Provide predefined color templates to change font/background colors” instead of the pattern “Offer a list of colors from where the font/background colors can be chosen” because of the following positive implications: efficiency of use, compatibility of the system with the real world, and clarity of information. The second option had more negative implications than the first one, such as difficulty in use by beginners and the constant need to resize the space reserved to the presentation of information.

We defined that the applications in the SBTVD need to have a high level of usability. There was a list of technology constraints, especially the ones related to memory and processing capacity. Besides that, graphical representations need to be simple because conventional TV sets do not support images as computer monitors do, and the TV luminosity is very different from the one in monitors; consequently, colors and texts appear differently.

Consider HCI Models and Use Cases

In this activity, analysts and usability experts elaborated use case and task models, and then changed them, when change requests were made after the evaluation of users in the end of the Inception phase. The requests resulted in changes in the models because they were changes in the functionality, such as: do not consider access to multiple applications simultaneously (technical constraint) and include personalized help. These changes reflected in the models and will be considered in the prototypes.

Analyze Existing Systems

In this activity, we researched on the Internet in order to find digital TV systems already in use. It was very difficult to find them because there are few systems available for access in the Internet. This analysis was used to identify some UI design patterns for the digital TV, such as: upper and bottom options bar, menu on the left, navigation icons, interaction buttons, and so on.

Consider Paper Sketches

After the analysis of existing systems, UI designers elaborated paper sketches (Figure 2). However, they needed to be redesigned after the evaluation of users in the end of the inception phase, which resulted in change requests.
Some change requests resulted in the following changes in the prototypes: transfer the bar from the top to the bottom of the screen, include the “TV” button in the bar when accessing an application or in the portal; include the “Portal” button in the bar when accessing an application, take off activated icons (because of technical restrictions), and give a preview of the requested options of personalization. However, other requests resulted in changes in the models as well as in the prototypes, such as the ones mentioned in the activity “Consider HCI models and use cases.”

Verify with Expert

In this activity, we performed heuristic evaluations with three experts who considered the usability of the paper sketches. They observed aspects, such as: navigation between views and if usability principles were applied. Besides that, the experts verified if all users’ goals, in terms of functionality (in the task models), were included in the prototypes.

Validate with Users and Customers

In meetings with the institutions participants of the project and with representatives of the Government users evaluated the elaborated prototypes.

Various change requests, as well as users’ preferences were identified. These requests resulted in updates in the models and in redesign of the paper sketches.

As examples of preferences, we point out the following: Include the “TV” and “Portal” in the remote control; the bottom options bar should overpass the application; and make available a set of options for inserting text, such as the one used in computer keyboards, the one used in mobile phones, and in alphabetical order.

Phase II: Elaboration

Use Design Patterns

In this activity, the UI design patterns, identified while analyzing existing systems, were evaluated and the UI designers started to design drawing prototypes using the design patterns.

Consider Drawing Prototypes

The UI designers used image editors, such as Photoshop® and Corel Draw®, in order to design the drawing prototypes (Figure 3), which followed

Figure 3. Drawing prototype: Personalization
the selected patterns, the updated task models, and paper sketches. In this prototype, the small view on the right shows the preview of the required personalization about the color of the screen before applying it.

Verify with Expert

The drawing prototypes were evaluated by experts (Figure 4), who observed various aspects, such as: layout, colors and fonts, UI design patterns, and usability principles applied.

Validate with Users and Customers

This activity is yet to be fully performed in this project, currently; we have finished the document that specifies the SBTVD graphical UI, which is going to be evaluated by representatives of the Brazilian Government.

We scheduled a workshop with the other institutions participants of the project to evaluate the drawing prototypes (Figure 5). They requested us to elaborate other alternatives of UIs (including association of options in the UI with options on the remote control), increase the size of the options and fonts in the upper bar, and change the way to differentiate the selected option.

Phase III: Construction

Implement and Integrate

The implementation of the portal has not started yet. However, the developers have been studying and implementing simple applications for the digital TV, such as three possibilities of insertion of text (the one used in computer keyboards (‘qwerty’), the one used in mobile phones, and in alphabetical order).

Elaborate Test Cases

The elaboration of functional test cases has started since the inception phase, when use cases and paper sketches were elaborated. Functional requirements were selected and the associated test cases were elaborated: structure applications, access applications, access help and personalization (Table 1).

Verify with Expert

In this activity, the programmers and the experts verify the applications using the test cases for guidance. Some of these evaluations were done in the small applications developed for insertion of text.

Figure 4. Verification with expert

Changes in font size |
| Pre-conditions | The user must be accessing the portal |
| Inputs | The user must select a type of personalization: Font color The user selects green |
| Expected results | The portal must present the personalized content with a green background color |

**Phase IV: Transition**

The usability experts and the developers have prepared the test environment. For that, they have: prepared the physical structure (e.g., TV, video camera, couch, computer to simulate the set-top box, etc.) and installed the necessary software (i.e., software to capture the user interaction with the TV, Linux Operating System, Java Virtual Machine, and applications to be tested).

A group of three usability experts were responsible for performing the following activities before the tests started: First, they defined a questionnaire to apply with users in order to understand their characteristics and familiarity to the DTV technology. Second, they selected appropriate metrics (e.g., number of errors, number of access to the help, etc). Third, they created a checklist based on Nielsen’s usability goals and on the metrics from the previous step. Fourth, they prepared the environment with a DTV, a couch, and a center table in order to make users feel at home. Fifth, they selected ten users with different profiles between the ages of 18 and 26.

When the users arrived, each one at a time was taken to the DTV room, where a usability expert explained the goals of the test; applied the questionnaire; and defined a specific goal to be achieved while interacting with the DTV. While the user interacted with the application, usability experts filled out the checklist in the visualization room, where we monitored the environment and the user with a camera and captured the interaction with the DTV using specific software.

**FINDINGS AND FUTURE WORKS**

After the tests, we evaluated the checklists and generated reports with solutions to the problems encountered during the tests. These reports contain comments about the icons, the navigation, and the help module of the portal application.

- No user realized the possibility of navigation through the numbers associated to each icon, which represents an interactive application (see Figure 6).
- When they were told about this, they used it and said it was very practical.
- For them, the icons were not a natural representation, but they did not want to give any opinion about possible solutions.
- Some users did not notice the application that was selected. They said it was better to have a big square around the icon instead of the current selection.
- When the users were confused and wanted some help, they did not look for it in the portal (the blue option in the bottom bar that activates the help module). Some users activated the menu button of the remote control and others waited for the evaluator to tell them what was necessary to do to obtain the help.

![Figure 6. The portal application](image)
Integrating Usability, Semiotic, and Software Engineering into a Method for Evaluating User Interfaces

As the bottom bar is used as a design pattern to put the navigation options, and as each option is different depending on the situation (the application being executed), the users got very confused. We realized they looked at this bar only once, and then they did not look at it any more. After memorizing the options, they wanted to use them all the time, but the color was different, so they made many navigation errors.

From the execution of these tests, we were able to quantify the results: 85% of the users found the system easy to use, easy to read, and easy to navigate, but on the other hand, 50% had difficulties in identifying that an option was selected and in getting out of an unexpected situation.

Our next step is to make the necessary changes that are related to improving the layout, color contrast, and icon selection. In addition, the next tests will be done with the elderly in order to investigate people who are not used to interaction devices.

CONCLUSION

In this chapter, we present a new method, which focuses on integrating different techniques of usability, semiotic and software engineering. The aims are to design usable UIs following a model-based UI design process and to facilitate the test process by using the evaluated HCI models. In this manner, we hope to contribute to the development of interactive systems that are easy for users to learn and use, and to help testers in performing their usability tests in an efficient manner.

As main contributions, we focus on evaluating the usability of UIs with the constant participation of users and customers. Besides that, the integration of various approaches results in positive outcomes for the prototypes, as well as for multidisciplinary team members, who are better integrated and can have their knowledge enhanced, since they are continuously exchanging information and experiences.

ABSTRACT

How can we design technology that suits human cognitive needs? In this chapter, we review research on the effects of externalizing information on the interface versus requiring people to internalize it. We discuss the advantages and disadvantages of externalizing information. Further, we discuss some of our own research investigating how externalizing or not externalizing information in program interfaces influences problem-solving performance. In general, externalization provides information relevant to immediate task execution visibly or audibly in the interface. Thus, remembering certain task-related knowledge becomes unnecessary, which relieves working memory. Examples are visual feedback aids such as “graying out” nonapplicable menu items. On the contrary, when certain needed task-related information is not externalized on the interface, it needs to be internalized, stored in working memory and long-term memory. In many task situations, having the user acquire more knowledge of the structure of the task or its underlying rules is desirable. We examined the hypothesis that while externalization will yield better performance during initial learning, internalization will yield a better performance later. We furthermore expected internalization to result in better knowledge, and expected it to provoke less trial-and-error behavior. We conducted an experiment where we compared an interface with certain information externalized versus not externalizing it, and measured performance and knowledge. In a second session 8 months later, we investigated what was left of the participants’
Guidance in the Interface

knowledge and skills, and presented them with a transfer task. The results showed that requiring internalization can yield advantages over having all information immediately at hand. This shows that using cognitive findings to enhance the effectiveness of software (especially software with specific purposes) can make a valuable contribution to the field of human-computer interaction.

INTRODUCTION

Humans interact with information in the world around them by taking it in, processing it, and outputting reactions. To process information, they use cognitive skills such as thinking, learning, reasoning, recognizing, and recalling, as well as metacognitive skills, which entail thinking about cognition (for instance, planning, strategizing, or choosing between reasoning or calculation types). Cognitive science studies these domains of human thought. Much research in this field is done through the analysis of subject reactions to presented information. This makes cognitive science a source of knowledge that could— and does—guide interface and system designers toward a more effective presentation of information in computer systems. We believe that utilizing cognitive findings to enhance the effectiveness of software can make a valuable contribution. Increasingly humans exchange information with the aid of computers, for instance, in education, entertainment, office tasks, information search, e-mail, and many other domains. Advances in computer and multimedia technology ensure that the format of this information is increasingly diverse using multiple media. Moreover, programs can have hundreds of functions. However, progression becomes difficult with this complexity of choices and representations. Harnessing this complexity to make it manageable for humans gave rise to the domain of “usability.” Soon, among other things, the importance of minimizing user memory load became apparent. This resulted in recommendations to simplify the interface, restricting available options to those needed to carry out the task at hand, and to keep options visible on the interface so users could interact on the basis of recognition rather than recall (Nielsen, 1994). In other words, the aim was just-in-time delivery of just the right information, obviating the need for memorization and extensive search in memory.

Our research does not aim at uncovering more principles that make systems even more usable, intuitive, or appealing. It goes beyond plain usability and focuses on how to shape interfaces that induce a user to learn cognitive and metacognitive skills, and thereby learn about the domain underlying the interface. We would like to find patterns of human behavior occurring with computer use, to find out what kind of behavior certain decisions in interface design provoke, not only during interaction, but also after delays and in transfer situations. In this, we feel that one continually has to consider the real purpose of the system. If a system ought to teach material to students or children, or needs to make sure that users do not mindlessly follow interface cues because the task to perform is of a certain crucial nature, then we should know what it is about an interface design that induces people to think and learn. In this chapter, the focus is on internalization and externalization of information, and how this may lead to different behavior on the user’s part. In the following sections, we explain the different terms used in this context. After this, we will look at the pros and cons of externalizing and internalizing information, and some effects of varying interface elements on learning and metacognitive processes. In the next sections we discuss an experiment on users’ behavior that two interface styles (internalization and externalization) provoke, and more specifically, the amount of planning and learning from the users’ side. In the concluding section, we discuss our findings and lay out our future plans.
EXTERNALIZATION VS. INTERNALIZATION INFORMATION: RELATED FIELDS

Visualization of task-specific information, thus minimizing user memory load, is often called “externalizing” the information (Zhang & Norman, 1994). Externalization of information can be contrasted with internalization of information, whereby certain task-related information is less directly available and needs to be internalized (inferred and stored in memory).

Early work of Simon (1975) examining advanced chess skills and strategies to solve the Tower of Hanoi puzzle had noticed the interdependence of “external memory” (perception, cueing recognition memory), and internal memory (recall memory). Norman (1988) argued for the need of a similar analysis for human-computer interaction. Tabachneck-Schijf, Leonardo, and Simon (1997) created a model in which distributed cognition was reified. For an example of distributed cognition, showing the interaction between internal and external memory in creating a Microsoft PowerPoint page, see Tabachneck-Schijf (2004). The question is, how much information should be internalized and how much should be externalized for an optimal task execution? Some research shows that the more information is externalized, the easier executing a task becomes (e.g., Zhang & Norman, 1994). Other research shows that externalizing all needed information seduces the user into mindlessly following the interface cues and learning or planning little (e.g., Mayes, Draper, McGregor, & Oatley, 1988). Yet other research shows that giving users incentives to plan and learn (i.e., internalizing information) pays off in better performance (e.g., O’Hara & Payne, 1999). Internalizing and externalizing information are related to, but not the same as, internal and external memory, internal and external cognition, and plan-based and display-based problem solving. All relate to having information in the head, be it in long-term or in working memory, versus information that is available via (direct) perception. Simon and colleagues refer to external memory as all information that can be made available for perception (e.g., Greeno & Simon, 1974). In practice, this comes down to all information that, within the task execution, can be made available for direct perception and working memory. Internal memory is all the information within long-term memory that can be made available to working memory.

External cognition is a term coined by Scaife and Rogers (1996) and refers to the interaction between internal and external representations (the latter being “external memory”) when performing cognitive tasks (e.g., learning). Scaife and Rogers provide a useful overview on the use of graphical representations in educational environments and outline a theoretical framework. They conceptualize how different kinds of graphical representations (e.g., diagrams, animation, and multimedia) are used during cognitive activities. The framework presents a set of core properties, of which the central one is computational off-loading (the extent to which different external representations reduce the amount of cognitive effort required for cognitive activities). This property was also mentioned by Greeno and Simon (1974) and Larkin (1989).

Plan-based and display-based problem solving relate to which source is used to draw information from. In plan-based problem solving, one uses detailed problem-solving strategies from (internal) long-term memory. Display-based makes little use of learned knowledge but relies on (external) interface information (Larkin, 1989; O’Hara & Payne, 1999).

Externalizing and internalizing information, finally, refer to making information available on external memory versus not making it available on external memory, thus requiring recording it on internal memory. We feel that studying the relationship between internalizing and externalizing information in order to find effects of interface
information on behavior and problem solving is an important first step.

**PROS AND CONS OF EXTERNALIZING INFORMATION**

In many instances, and for many purposes, externalizing information and thereby reducing working memory load is indeed a fine idea. Externalizing interfaces “take the user by the hand,” limit choices, and provide feedback. What information should a computer system offer? If one is working with a dynamic visual display on a problem-solving task, problem states are directly visible and elements that are normally stored in working memory can now be read from the display. A way to facilitate reduction of memory load is by visually showing what possible steps can be taken to go from one state to the other in the problem space (for a problem space, see Figure 4). It prevents users from internalizing a great deal of information. Other ways to reduce memory load and support explorative behavior are, for instance, guidelines such as “keep the number of possible operations small,” “make the possible operations distinguishable,” “make clear what the consequences of every action will be,” “make the effects of actions visible once they have been executed,” or “make actions easily undoable to make it safe to experiment” (Lewis & Polson, 1990; Van Oostendorp & De Mul, 1999).

Systems such as cash dispensers, automated airline check-in systems, and so forth should be designed in such a way that users can simply and easily follow the interface cues. Other examples are wizards and help options. Graying-out menu items that cannot be used at that moment is also an example of externalizing information. For example, in Word, you cannot select “paste” from the “edit” tab in the menu when nothing is copied or cut first. “Paste” is shown in gray, indicating that the command exists, but that using it is impossible at the moment. In various lists of user interface guidelines similar issues, such as “visibility status” and “visual feedback” are mentioned.

Interfaces that externalize do minimize working memory load. For instance, Larkin (1989) considered the role played by differences in external displays in cognitive problem solving, finding that making information visible, enabling “display-based problem solving,” helped people recover from interruptions in work. As mentioned,

---

**Figure 1. Examples of externalization by graying-out items**

![Example of externalization by graying-out items](image-url)
Guidance in the Interface

Zhang and Norman (1994) showed that the more information was externalized, the easier solving a problem became.

Van Joolingen (1999) studied the idea of learners actively engaging in order to learn about the properties of what is underlying a certain domain. He mentioned the reduction of memory load in the context of research on the role of learner support in discovery learning. Discovery learning assumes that learners take an active role and construct their own knowledge base by interacting with a domain, and inferring rules from the results of these interactions. Active involvement of the learner would result in a better base of knowledge in the learner as opposed to more traditional ways of learning. The question is, of course, how to accomplish this behavior from the users’ side. He addressed the issue of supporting discovery learning by means of cognitive tools. Cognitive tools were defined as instruments that support cognitive processes by relieving working memory and which can aid the learner to direct the process, to perform a part of it, or to externalize part of processes and memory.

However, externalization of information also appears to have disadvantages. There is some evidence that during computer-based problem solving, with most information externalized users simply “follow the yellow brick road.” Users search the interface for cues and reliably find them, perform an action that alters the interface, thus enabling another search for cues and so, applying simple perception-based means-ends analysis, eventually complete the task. If the task appears to be completed correctly, then it follows that users will not be triggered to plan, learn, or look for underlying rules or reasons, and also, that people can only carry out a sequence of actions if the interface supplies the needed cues. In a study comparing memory of users for a sequence of actions, researchers found just that (Mayes et al., 1988). Users using a command-style interface (e.g., LaTeX) with most cues externalized could not. Also, external cues can easily lead subjects to incorrect actions. Tabachneck (1992) found that when the needed information was externalized on a graph so that simple perception yielded the correct answer, subjects gave the correct answer. However, in different representational formats simple perception yielded an incorrect answer; here subjects also followed the interface cue and gave the incorrect answer. In summary, externalizing information does decrease memory load, but drawbacks are that people are likely to perform continual trial-and-error recognition-based search and not learn or plan. Also, the external information may lead to the wrong answer and thus to errors. Task execution via externalized information may also be very resistant to speeding up. We feel that there are many tasks for which, during task execution, internalization of information is desirable. Examples are tasks with the purpose to acquire knowledge or skills, be they cognitive or metacognitive; tasks one does often, and consequently speeding up and reducing errors is desirable (such as booking a trip for a travel agent), or tasks where the cost of errors is high (e.g., controlling nuclear power plant or flying an airplane). When looking more specifically at problem-solving tasks, planning and learning are thought to be essential factors. It is therefore desirable to do more research on how interface design, internalizing, and externalizing information can stimulate people to do more internalization. Not externalizing all information may stimulate self-directed search, more active planning, and learning.

VARYING ELEMENTS AND (META)COGNITIVE PROCESSES

O’Hara and Payne (1998) and Trudel and Payne (1996) found that when people are induced to plan, too strong a reliance on external information
leads to negative effects regarding planning and transfer of skills. Inducing people to do plan-based problem solving would lead, they hypothesized, to internalization of metacognitive and cognitive knowledge, in turn improving task performance and easier recovery from errors (see also Payne, Howes, & Reader, 2001). O’Hara and Payne’s (1998) experiments showed that plan-based activity did lead to shorter solution routes and easier recovery from errors, while a display-based strategy involved more steps because of more (trial-and-error) searching. O’Hara and Payne used an interesting methodology to get people to plan more. In one of two conditions, they made the interface harder to use by imposing delays on operators. They reasoned that subjects plan more when there is something at stake: here, reducing costly delays. A similar observation was made by Svendsen (1991). Using the Towers of Hanoi problem, a high-cost interface yielded improved understanding of problems. In the studies of Payne and colleagues, the amount of information externalized was not varied. We felt that not externalizing all information will similarly stimulate students to self-initiate a search for the missing information to plan and to learn.

In the first session of our experiment, discussed next, we researched whether varying the amount of externalized information would have an effect on performance, planning, and learning while solving a problem. In the second session we assessed what was left after 8 months of what subjects had learned in the first session and whether this still had an effect on task performance. Details follow.

**EXPERIMENT SESSION 1**

**Hypotheses**

1. **Externalization will initially yield better task performance than internalization.** Knowledge is yet to be acquired, so guidance by indicating the legality of moves will help externalization subjects.

2. **Internalization yields better task performance later, especially after a severe distraction.** After a while, subjects will have learned to solve the puzzle. Internalization subjects had no guidance and had to acquire the solving skill by themselves. They will have stored the rules in long-term memory more solidly, and have the needed information more readily available and thus perform better later, especially after an interruption erased working memory. Because of the guiding nature of the interface, externalization subjects will plan and think less than the internalization subjects, therefore work more on the basis of trial and error and consequently display worse performance.

3. **Internalization yields better knowledge.** Not having externalized information available will motivate a subject to start planning on the basis of self-acquired rules. After the
experiment, we expect the explicit knowledge of rules to be memorized better by internalization subjects. There may also be a difference in implicit procedural knowledge, but we expect it to be smaller since both groups will have played the puzzle a similar number of times.

An experiment was conducted in which subjects solved a puzzle on a PC nine times in two conditions: internalized and externalized. In terms of performance, we expect the outcomes to take the following course:

- **Phase 1:** Three trials. Subjects do not have any needed knowledge available yet, externalization offers more interface cues, and will result in better performance.
- **Phase 2:** Three trials. Performance in the two conditions will be equal by this time, because internalization subjects acquired internal knowledge that compensates for the interface cues.
- **Interuption:** This task is sufficiently demanding that all of the working memory is erased.
- **Phase 3:** Three trials, after the interrupting distraction task. Internalization subjects perform better because of better internalized knowledge and a more elaborate plan.

**Materials**

Our problem-solving task, “Balls & Boxes” (B&B), is an isomorph of the classic puzzle “Missionaries and Cannibals” (M&C). Five missionaries and five cannibals are standing on a riverbank, and all have to reach the other bank by boat. Constraints are that the boat only holds three creatures, and the minimum to sail is one, because the boat cannot move by itself. Furthermore, the cannibals can never outnumber the missionaries at any place (except when there are zero missionaries), or the missionaries will be eaten. Our B&B problem (Figure 3) uses exactly the same problem space (Figure 4), but is more abstract.

We made the puzzle more abstract to reduce the many common knowledge elements in the classic M&C: cannibals eat people, boats cross rivers, boats cannot sail empty, and so forth. Using boxes, blue and yellow balls, and a dish instead, we offer a semantically less rich problem, avoiding the rules to be learned and remembered too easily.

The rules of B&B were as follows:

1. Balls should be transported using the dish.
2. You can transport at most three balls at a time.
3. To move, the dish must contain at least one ball.
4. The dish has to reach the boxes in turn.
5. There can never be more blue than yellow balls in the dish (except when there are zero yellow balls).
6. There can never be more blue than yellow balls left in either of the boxes (except when there are zero yellow balls).

Rules 5 and 6 are the most problematic rules, making no semantic sense whatsoever. In our puzzle, it was possible to consult all the rules, but having access to these does not imply that one knows how to solve the problem, and surely

**Figure 3. The Balls & Boxes puzzle**
Guidance in the Interface

not how to solve it in the most efficient manner. Below we depict the formal problem space of the puzzle (Figure 4). The numbers indicate the number of blue and yellow balls in the left and the right box, and the “∗∗” indicates on which side the dish is (see the legend of Figure 4). The shortest path from “A” to “N” takes 11 moves. There are also states of the puzzles that we call “dead-end states,” such as states D, E, G, J, K, and M. These states are not on a direct solution path, and force backtracking.

The interface controls of the puzzle were straightforward (Figures 5 and 6). To get balls into or out of the dish, blue or yellow up-arrows or down-arrows had to be clicked. To move the pink dish horizontally, one had to click a pink arrow (left or right). After the dish was moved, the balls automatically dropped into the box. To consult the rules one clicked on the rules tab. The rules screen overlaid the puzzle screen. The puzzle was designed in two versions:

1. **Internalized:** All arrows were always colored (Figure 5) and clickable, providing no information about the legality of moves (performing illegal moves is possible). One could click all buttons at all times; however, illegal moves would be carried out only partially. For instance, if one wanted to transport the dish empty from left to right and clicked the right pink arrow, the empty dish would move to the right. Then, an error

---

**Figure 4. Problem space of the Balls & Boxes problem**

![Figure 4. Problem space of the Balls & Boxes problem](image-url)
Guidance in the Interface

notification would pop up saying, “This is not possible.” By clicking “OK” in the dialogue box, the program would undo the move.

2. Externalized: The arrows are colored (and thus clickable) only when an action is legal. The arrows are grayed-out (unclickable, as in Figure 6) when a move is illegal. For instance, in Figure 6, moving the dish empty from left to right is illegal (violating rule 3), externalized by graying-out both pink arrows. It is now only legal to move balls up into the dish.

Subjects and Design

Thirty subjects of age 19–28 (mean age 21.8), experienced with PCs, were recruited at Utrecht University. Subjects were paid 5. The puzzle, a Java-applet, ran on a Pentium IV 2.0 GHz PC with a 17” monitor. Our design has one random-as-

Figure 5. Internalized version: No information whether an action is possible (no gray-out)

Figure 6. Externalized version: Information whether an action is possible (grayed-out)
assignment between-subjects independent variable: internalization versus externalization. Among the dependent variables were the following:

- Performance measures (logged)
  - Number of puzzles subjects solved per phase (maximum three per phase)
  - Speed: time needed to solve the puzzles
  - Reaching dead-end states. These are puzzle states that are off a direct solution path, indicating trial-and-error search (states D, E, G, J, K, and M in Figure 4)

- Knowledge test: After the puzzles, we measured implicit and explicit knowledge of the rules and shortest-path solutions of the problem, using a paper questionnaire.

- Attitudes: Likert-scale questions concerning perceived amount of planning, feeling lost during interaction, and other such measures.

**Procedure**

The experiment was conducted in the usability lab at the Center for Content and Knowledge Engineering, Utrecht University. We informed the subjects of the course of the experiment, and gave a brief oral explanation of the interface and a short demonstration. The experiment consisted of nine puzzle trials, divided into three equal phases, and a 10-minute distraction task between phase 2 and 3. The maximum time for each trial was set at 7 minutes. Slightly different starting situations of the puzzle were used to avoid subjects simply repeating actions (states A, B, and C in Figure 4). Also, in the second phase, the playing direction of the puzzle was reversed to right to left. In the third phase, the playing direction was set to left to right again. After the last trial, subjects filled out a knowledge test (score 0–8) consisting of four multiple choice and four open questions with screenshots of puzzle situations. They had to judge and explain whether and why certain actions were possible (implicit knowledge), and recall the rules (explicit knowledge). Subjects also rated how clear the rules were for solving the problem.

**RESULTS EXPERIMENT, SESSION 1**

Number of Puzzles Solved per Phase

Subjects could attempt to solve three puzzles per phase. A MANOVA (analysis of variance) showed a significant main effect of phase on the average number of puzzles solved, $F(2,56) = 53.74$; $p < .001$ (Figure 7) (pointer to figure). The number of puzzles solved (out of three) improved in later phases, indicating a learning effect. Post-hoc comparisons showed that only the difference between performance in phase 1 and phase 2 was significant ($p < .05$) (Figure 8) (pointer to figure). Although the graph suggests an overall better performance for internalization ($M = 6.93$, $SD = 2.05$ vs. $M = 6.33$, $SD = 3.09$), this did not reach significance. There were no interaction effects.
Guidance in the Interface

**Time Needed for the Puzzle Trials**

A MANOVA showed a main effect also for phase on average solving time, $F(2,42) = 35.16; p < .001$. The time subjects needed to solve puzzles lessened in later phases, also a learning effect. Post-hoc comparisons showed that all subjects needed significantly more time in phase 1 than in phase 2, and also in phase 2 than phase 3.

The graph suggests that internalization subjects need some more time on average, but ANOVA showed that this was just a trend ($F(1,21) = 2.79, p = 0.11$). Looking closer, it was only in the beginning, in phase 1, that internalization subjects needed more time ($M = 238.77, SD = 62.20$) to solve the puzzles than externalization subjects ($M = 186.77, SD = 67.08$). This difference was significant, $t(21) = 1.94, p = 0.03$ (one-sided). After this first phase, the differences were minuscule and no longer significant.

**Dead-End States**

Below is the number of times per phase subjects reached dead-end states.

A MANOVA showed an interesting nearly significant main effect of interface style (Figure 9). Overall, externalization subjects reached more dead-end states ($F(1,28) = 3.58; p = 0.06$). In addition, there is a trend for an interaction effect of phase and version ($F(2,56) = 2.11; p = 0.13$). Internalization subjects significantly improved from phase 1 to 2 ($M = 11.4, SD = 4.70$ and $M = 3.4, SD = 3.18$), $t(14)=5.80, p = 0.00$, one sided). This is an improvement of eight states. They also improved from phase 2 to 3 by almost two states, nearly reaching floor level ($M = 3.4, SD = 3.18$ and $M = 1.47, SD = 2.07$), $t(14)=1.96, p=0.04$, one sided. Externalization subjects improved by 6.2 states from phase 1 to 2 ($M = 12.67, SD = 6.91$ and $M = 6.47, SD = 7.11$), $t(14)=2.74, p = 0.02$, one sided. But after the interruption, it was different. From phase 2 to 3, they did not further improve. On the contrary, in phase 3 they reached more dead-end states than before, although not significantly so. Here in phase 3 the difference between internalization ($M = 1.47, SD = 0.53$) and externalization ($M = 7.73, SD = 10.64$) was significant, $t(28)=2.24, p = 0.04$. Externalization subjects reached more than six more dead-end states in phase 3 than internalization subjects.

**Knowledge Test**

Before measuring knowledge of the rules and states, we confirmed that there was no difference in the number of times subjects in both conditions consulted the rules. The knowledge test that
subjects received after the experiment consisted of several procedural knowledge questions and one explicit knowledge question. The Balls & Boxes puzzle contained more than 30 legal states (Figure 4). There were seven procedural implicit knowledge questions about seven of those states (open and multiple choice) in which subjects were visually presented with a puzzle state. They had to judge whether certain moves led to the solution, and explain why. The scores on those seven questions were high for both internalization (M = 6.3, SD = 0.96) and externalization subjects (M = 5.8, SD = 1.20), considering that the maximum score was seven. There was a trend that internalization on average scored higher than externalization on the procedural knowledge questions (t(28) = 1.17, p = 0.12).

To test the explicit rule knowledge, the possibilities were limited. The puzzle had only few rules, some of which (rules 1 to 4) were extremely easy to grasp and remember. Rules 5 and 6 are more crucial and define the difficulty of the puzzle. They can be merged to just one rule: “Blue balls can never be in the majority at any place, except when there are only blue balls (zero yellow balls).” Subjects were asked about this rule with a multiple-choice question. All internalization subjects answered this question correctly, whereas of the externalization subjects only 60% answered it correctly. This difference was significant (Phi = -.50, p < 0.01). Furthermore, subjects had to estimate the clarity of the rules. They rated the question “the given rules were clear enough to solve the problem” (score range 1–5). Internalization subjects found the rules clearer than the subjects from the externalization condition (M = 4.13, SD = 0.52 and M = 3.53, SD = 1.25), t(28)=1.72, p = .04 (one-sided).

**SUMMARY EXPERIMENT SESSION 1**

Our first hypothesis stating that initially externalization yields better performance was only partly supported in terms of the time subjects needed. Internalization subjects did take more time in the first phase. Other measures were in the expected direction, but not significantly so. Unexpectedly, externalization yielded no better performance in terms of puzzles solved in the beginning, as we expected.

The second hypothesis stating that internalization yields better performance in a later stage was partly supported. We saw that the time subjects needed stabilized, and the same was true for the number of trials solved per phase. However, we also looked at performance in a more delicate manner, not in terms of time or correctness, but at how, via what route, subjects reached their goal. We introduced the measure “dead-end states” to inform us as to how subjects behaved, in terms of the insight they had, the “smartness” of their route. We assumed that internalization subjects do some smarter, more elaborate planning, while externalization subjects are expected to solve more by trial and error and on the basis of interface cues. It showed that internalization subjects performed better after the interruption and reached those dead-end problem states less often in all three phases (indicating less “lostness”). Furthermore, there was also the trend-like interaction that after the interruption, internalization subjects kept improving, while externalization subjects fell back, reaching more dead-end states than they did before. This confirms our expectation that after the interruption, internalization subjects would continue to work on the basis of the plan-based strategy as they did before. Externalization subjects, on the other hand, perform no better after the interruption. They fell back to depending on the interface, having a less elaborate plan.

The third hypothesis in which we expected that internalization would result in having better knowledge was supported. We also assumed that internalization subjects, who could rely less on interface information, had to build a stronger, more elaborate plan. Though when testing implicit knowledge both groups scored equally
high, with a trend advantage for internalization subjects, when asked about explicit knowledge of the crucial rule that defines the difficulty of the puzzle there was a significant difference. All the internalization subjects could correctly answer this question, whereas only 60% of the externalization subjects could—in spite of having the rules readily available for consultation and consulting them as often as internalization subjects. Furthermore, there was also the tendency that internalization subjects rated the clarity of the rules higher. This is intriguing, because in the externalization version of the puzzle subjects had interface feedback and were able to consult the rules. Internalization subjects, who only had the rules and no interface help found the rules clearer. We carefully interpret the latter two findings as indicators of better understanding in the internalized condition.

**EXPERIMENT SESSION 2**

We were curious to see how stable this better knowledge provoked by internalization was, and therefore decided to conduct a second session after a delay of 8 months. We invited the same subjects of experiment 1; 14 of the 30 were available. There were two reasons for this rerun. First, to see whether the better knowledge measured in the internalization subjects had endured, we asked subjects to solve B&B five times (experiment 1 showed three to four puzzles suffice for all subjects to be able to solve the puzzle within the allotted time). Second, to see whether the better knowledge might result in better performance on a transfer task, we also confronted subjects with a transfer problem. Transfer problems require subjects to apply acquired skill on a different task of the same nature. To be able to measure differences in performance between the two initial groups (internalization and externalization) on the same material, we presented all subjects with the same material this time, one interface style, namely, externalization. Note that the internalization subjects had to make a change in interface style.

**Hypotheses**

1. Because internalization subjects still have better memory of the rules and solution, they will perform better. We expect the internalization subjects to solve the puzzle faster initially because of their better knowledge of the rules. They will be faster in recollecting knowledge needed to solve the puzzle. After a while, we expect the two groups to perform more or less equally on this puzzle, like in session 1.

2. Internalization subjects will perform better on the transfer tasks. After five times of B&B, we expect the two groups to perform at the same level. But when confronted with transfer tasks (that have similarities but also a few differences), we expect internalization subjects to perform better, again because they possess better knowledge of the rules.

**Materials**

To test knowledge retention, all subjects first solved the B&B puzzle in the externalized version five times. To test transfer performance, we used another puzzle of the same M&C “family,” but with varying characteristics. We first used a quite literal version of M&C, which was further away in terms of transfer.

**Balls & Boxes**

The only difference between this and the previous B&B was that the rules were not consultable anymore, so we could obtain a more pure measure of retention. All subjects received the same externalized version. This meant that attempting illegal moves (moves that violate rules) was not
possible, as the externalized interface only allowed legal moves.

Missionaries and Cannibals

The second problem was a transfer task, ironically the original version of the M&C. It was a game that literally shows missionaries, cannibals, a river, and a boat. The solution algorithm to this problem was the same as B&B, but there were some difficulties that did not exist before. The most important one is that there were not five of each entity as before, but three, and the playing direction was always from right to left (Figure 10). Although it might seem that one can solve the three-creature problem faster, this is not so—the shortest path to the solution is also 11 moves. Also, unlike in B&B, in this game attempting illegal moves does not lead to an error message, but subjects would “die,” as in a computer game, and the game would start over. Errors thus had more severe consequences, and subjects needed to exercise caution. Subjects had to solve the problem as many times as they could in 8 minutes.

Subjects and Procedure

Fourteen of the 30 subjects from session 1 were willing to participate a second time. Luckily, seven of them had worked with internalization, and seven with externalization in session 1. We confirmed that these 14 subjects were subjects who performed “normally” (no extreme scores) in session 1. The experiment consisted of two parts:

1. B&B (five times). The maximum time for each trial was set at 7 minutes. Slightly different starting situations of the puzzle were used to avoid subjects simply repeating actions.

2. M&C (8 minutes).

After completing the experiment, subjects received a 5 reward.

RESULTS EXPERIMENT SESSION 2

• Balls & Boxes. Encouraging results were found concerning solving the puzzle correctly again the first time. After not having seen the puzzle for 8 months, it took the internalization subjects only half the time used by the externalization subjects to solve the first B&B puzzle (M = 432 sec, SD = 314 and M = 778 sec, SD = 397). This difference was significant, t(12) = –1.81, p = .05. There were no further significant differences between the two groups. After the first puzzle, as expected, all subjects solved the remaining four trials of B&B puzzle equally well, just as 8 months ago.

• Missionaries & Cannibals. This puzzle was a bit further in transfer. The graphical characteristics of this puzzle differed considerably. Still the algorithm to solve it in itself was the same, but the number of creatures to transport was different, and also the maximum number of creatures allowed in the boat. Although the shortest solution
path is the same length as B&B, the problem does have a smaller problem space. The same basic concept had to be applied to a situation that differed at face value, and also underneath. Out of our 14 subjects, 10 managed to solve this puzzle one or more times. Just as in the B&B puzzle, internalization subjects solved it the first time faster (M = 176 seconds, SD = 72.5 vs. M = 302.8, SD = 202.7), though it was just a trend, t(8) = –1.44, p < 0.10 (one-sided). Moreover, internalization subjects managed to solve the puzzle three times more often (M = 4.83, SD = 1.94) in the 8 minutes than externalization subjects (M = 2.5, SD = 1.73). This was significant, t(8)= 1.94, p < .05 (one-sided).

SUMMARY EXPERIMENT SESSION 2

Eight months is a long time, but still the interface style subjects received in session 1 appeared to make a difference. Subjects were not told at the first session that they would be asked to play the puzzle again, and when we approached them, we explicitly told them it was not the same experiment they had participated in. Upon being confronted with the puzzle again, the subjects had to recollect the rules and solution strategy from their long-term memory.

The two groups both worked with an externalized version this time and had exactly the same information. We looked at how long it would take subjects to remember how to do this correctly. It showed that in solving the first B&B again, internalization subjects were indeed significantly faster, almost twice as fast, in fact. This is all the more remarkable given that these subjects received, to them, an unfamiliar interface—externalized rather than internalized. After that first success, the performance of both groups equalized. This is coherent with the results from the first session, where stabilization in performance also occurred. The above finding supports our first hypothesis of experiment 2 stating that internalization subjects would still have a better memory of the rules and solutions of the puzzle.

The M&C puzzle that subjects received was the same for everyone. It can be regarded as an internalization version (no direct interface clues were available, all controls were available all the time). Also here there were some interesting results. The subjects that worked with the internalization version of B&B managed to solve this puzzle three times more often than externalization subjects, and this was significant. Furthermore, just like in B&B, internalization subjects needed less time to solve the problem the first time, although this was just a trend. It supports the second hypothesis stating that internalization subjects will perform better on a transfer task. In summary, we demonstrated that the interface style subjects worked with 8 months ago still appeared to be of influence months later, both in solving the same puzzle again as in solving a far transfer puzzle. We take it as encouraging support for the better memory of knowledge provoked by the interface style subjects worked with.

GENERAL DISCUSSION ON THE TWO SESSIONS

We analyzed the influences that externalizing certain information on the interface, thereby making it visible, or not externalizing it has on performance and knowledge acquisition in a problem-solving task. Furthermore, we looked at the long-term effects after 8 months, and at the issue of transfer. Both in session 1 and in session 2, the delayed session, NOT externalizing information led to enduring advantages in performance and knowledge, while externalizing information merely led to a fleeting advantage at the very start of session 1.

According to Zhang (1997), the more information is externalized, the easier performing a task becomes. We hypothesize, however, that being
Guidance in the Interface

led by the interface also incurs a cost, namely, a lessening of metacognitive activity such as planning, and consequently, less learning. In such situations as where learning is required, transfer is at stake, or the task is prone to interruptions, planning, learning, and in general, getting to know more about the structure of the task at hand are desirable outcomes. Surprisingly, performance measures such as time needed to solve the puzzles and number of correctly solved puzzles were not much influenced by the interface style—if anything, the internalization group was at an advantage. Zhang's (1997) prediction was not confirmed. We feel that the attention of users in the externalization group was immediately taken by the guiding nature of the interface, and as they were not confronted with actual mistakes (one could not make illegal moves, only inefficient legal moves were allowed), they simply kept on solving without feeling a need to figure the problem out more. Subsequently, less active learning took place. This idea of attention taken by an interface fits with Carroll and Rosson's (1987) paradox of the active user—users of computer systems are so consumed with immediate productivity that they are not motivated to take time to learn better ways of accomplishing a task.

Contrary to the externalization group, the internalization group was confronted with errors for which an explanation was not immediately available. These subjects incurred a cost when making errors: a dialog box popped up which they had to click away, and their attempted move was reversed. Though both groups consulted the rules sheets equally often, this cost probably contributed to motivating the internalization subjects to study the rules better in order to avoid incurring the cost. We found that the internalization group possessed better explicit knowledge of the rules and engaged in more planful problem solving. Applying more metacognition to avoid a cost concurs with the findings of O'Hara and Payne (1998, 1999).

During session 2 we found that the effects found in session 1 were still present. Again, only the internalization subjects from months ago showed advantages. This group was both faster in solving the same problem again, and also faster in figuring out the solution to a transfer task. It is remarkable that the influence of working with one interface or the other has effects even after such a long time.

In general, it was surprising for us to see that externalization showed even less advantage than we thought, almost none, to be precise. We expected externalization at least to be of help in the beginning when users were not familiar with the system and the problem. It was, but only in time taken on the first few trials—and this was just a trend that was not confirmed in the number of puzzles solved correctly. This very small and fleeting advantage did not concur with Zhang's (1997) findings. Please note that our type of externalization parallels Zhang's more physical type: both restrict the number of illegal moves that can be made, but do not alter the problem space or give cues as to what the shortest path is through the problem space.

We find the results so far encouraging in that lessening the amount of externalized knowledge apparently can encourage cognitive and metacognitive behavior. Moreover, one can be very precise about which information not to externalize—in other words, this way the information to be learned can be manipulated. Therefore, we feel that the issues of manipulating the amount of externalization in interfaces deserve more attention. In the context of current technology and the widespread use of computer systems in virtually all domains, we are convinced that understanding how the system’s users will perceive, reason, and interact with the system can be crucial. The implications of the findings so far and the ones in the future can be valuable for development of applications where active engagement and learning from users is the aim. Examples are systems to teach material to students or children,
or situations where it is important that users are not “kept” stupid by the software. In certain situations, users of a system need to understand the underlying structure/rules of the system because the tasks are of a crucial nature. To accomplish this we have to look beyond plain usability and common sense and better scrutinize the interaction between internal memory and cognition on the one hand and external memory and recognition and perception on the other hand. We believe this can, for certain types of systems, enhance the effectiveness in achieving their targets.

FUTURE TRENDS

There are still many challenges in human-computer interaction and many issues that need to be explored. Understanding how users will react to interface information (on the basis of cognitive findings) is one important issue in attuning software to its purpose, thereby allowing it to achieve its goal. In the future, we will further investigate this issue by exploring behavior in different types of more realistic planning-related tasks. As a more realistic planning task, we think of, for example, spreadsheet or drawing applications where actions are less repetitive, more complex, and could be part of a real job. We are currently designing such an environment.

Chapter 2.8

Ergonomic User Interface Design in Computerized Medical Equipment

D. John Doyle
Cleveland Clinic Foundation, USA

ABSTRACT

Current statistics suggest that preventable medical error is a common cause of patient morbidity and mortality, being responsible for between 44,000 and 98,000 deaths annually, and resulting in injuries that cost between $17 billion and $29 billion annually. An important approach to tackling this problem is to apply system design principles from human factors engineering (ergonomics). By doing so, systems and equipment become easier for people to work with, ultimately reducing the frequency of errors. In particular, in the case of medical equipment, the design of the user interface can impact enormously on its successful use. In this chapter we consider some of the elements of good and bad medical equipment design, using examples drawn from the literature and elsewhere. The concept of ecological interface design is also discussed, and some practical design guidelines are provided.

INTRODUCTION

American statistics suggest that preventable medical error is the eighth leading cause of death, being responsible for between 44,000 and 98,000 deaths annually, and resulting in injuries that cost between $17 billion and $29 billion annually (Kohn, Corrigan, & Donaldson, 1999). Experts have often stated that an important approach to improving patient safety is to apply system design principles from human-factors engineering (ergonomics; Kohn et al.; Leape, 1994). Human-factors engineering is a relatively young scientific discipline that focuses on those factors that affect the performance of individuals using systems or equipment (Kroemer, 2001). The product may be as simple as a spoon or an office chair, or as complex as an aircraft carrier, but in all cases the goal is to design products to conform to human nature rather than merely expect people to adapt to technology. By doing so, systems and equipment become easier for people to work with, ultimately reducing the frequency of errors.
In the case of medical equipment, the design can impact enormously on its successful use. In particular, errors in operating such equipment are often caused, at least in part, by the design of the user interface. Of course, such errors can not only hamper patient care, but in some cases can even lead to injury or death. It is obviously important that medical equipment be designed with special consideration given the impact of design on safe operation. Thus, the user interface for medical equipment should be straightforward and intuitive: If its operation is excessively complex or counterintuitive, safety can be compromised. Human-factors techniques have been applied to other industries, such as nuclear power and aviation, and have been very successful in reducing error and improving safety in these contexts. Note also that in addition to increasing safety, an added benefit of using good ergonomic design practices is the likelihood that training costs will be reduced.

**BAD DESIGN EXAMPLES**

Examples of perplexing, arcane, and hazardous designs produced in violation of ergonomic principles are not hard to find. For instance, Michael J. Darnell’s Web site www.baddesigns.com offers a collection of frequently humorous examples. But when bad designs in medical equipment lead to injury or death, the situation can be far from amusing. This is sometimes the case for computerized medical equipment.

In one case reported on the U.S. Food and Drug Administration Web site (http://www.fda.gov), a patient was overdosed after a nurse read the number 7 as a 1 in the drug-infusion pump display. Because the flow-rate display was recessed, the top of the 7 was blocked from view at many viewing angles.

In another case report from the same source, a physician treating a patient with oxygen set the flow-control knob between 1 and 2 liters per minute, not realizing that the scale numbers represented discrete, rather than continuous, settings. Unbeknownst to the physician, there was no oxygen flow between the settings, even though the knob rotated smoothly, implying that intermediate settings were available. The patient, an infant, became hypoxic before the error was discovered. One solution could have been a rotary control that snaps into discrete settings.

In yet another case, a patient on a ventilator died following the accidental detachment of the ventilator tubing from the humidifier. Unfortunately, an alarm did not sound because the pressure-limit alarm setting had been set so low that it was essentially nonfunctional.

Finally, Figure 1 illustrates a less hazardous example drawn from personal experience.

A series of reports from the laboratory of Dr. Kim Vicente of the University of Toronto have looked at user-interface issues for patient-controlled analgesia (PCA) equipment (Lin, Isla, Doniz, Harkness, Vicente, & Doyle, 1998; Lin, Vicente, & Doyle, 2001; Vicente, Kada-Bekhaled, Hillel, Cassano, & Orser, 2003). PCA is a computer-based medical technology used to treat severe pain via the self-administration of analgesic agents such as morphine. Potential benefits include superior pain control, automatic documentation, and improved utilization of nursing resources.

Unfortunately, however, one of these units (Abbott Lifecare 4100 PCA Plus II) has been linked to a number of overdose deaths. This machine is easily set up incorrectly by caregivers, who must manually enter the PCA parameters, and a number of patients have received drug overdoses as a result of user errors when using this product: the insertion of a 5 mg/mL morphine cartridge when the machine is expecting a 1 mg/mL concentration, or the acceptance of the default (initial) drug concentration when the correct action is to scroll up to the correct value, among other errors.

In the latter case, when nurses program the drug concentration, the Lifecare 4100 display shows a
Ergonomic User Interface Design in Computerized Medical Equipment

Figure 1. The user interface for medical equipment should be straightforward, friendly, and intuitive. Also, rarely is the operating manual available to the end user, which makes the labeling of the controls especially important. Consider then the user controls shown for this operating-room table in use at the author’s facility. The top and bottom left-hand controls lower the head and feet, respectively, while the right-hand controls raise the head and feet. But what if the entire operating table is to be raised or lowered, which is by far the most common request from the surgeon? It turns out that the entire table is raised by pushing both right-hand buttons, while the entire table is lowered by pushing both left-hand buttons. This arrangement makes sense if one thinks about it for a while, but an intuitive interface should not require a lot of thinking. Furthermore, there is plenty of space available on the control panel to add two extra buttons.

particular concentration (e.g., 0.1 mg/mL). Nurses can either accept this initially displayed value or modify it using the arrow controls. The critical flaw in the design is that in this situation, the Lifecare 4100 offers the minimal drug concentration as the initial choice. If nurses mistakenly accept the initially displayed minimal value (e.g., 0.1 mg/mL) instead of changing it to the correct (and higher) value (e.g., 2.0 mg/mL), the machine will run as if the drug is less concentrated than it really is. As a result, it will pump more liquid, and thus more of the drug, into the patient than is desired.

Aware of the dangers of the Lifecare 4100, Lin, Isla, et al. (1998) and Lin, Vicente, et al. (2001) studied the unit using cognitive task-analysis techniques. Based on this analysis, the interface was then redesigned “to include a dialog structure with fewer steps, a dialog overview showing the user’s location in the programming sequence, better command feedback, easier error recovery, and clearer labels and messages” (Lin, Isla, et al., 1998, p. 253). Studies of the new interface showed significantly faster programming times, lower mental workload, and fewer errors compared to the manufacturer’s original interface. Regrettably, the improved interface design was not used by the manufacturer.
DESIGN GUIDELINES

The U.S. Food and Drug Administration has offered a number of guidelines to help with the design of medical equipment, such as the following (adapted from http://www.fda.gov):

- Make the design consistent with user expectations; both the user’s prior experience with medical devices and well-established conventions are important.
- Design workstations, controls, and displays around the basic capabilities of the user, such as strength, dexterity, memory, reach, vision, and hearing.
- Design well-organized and uncluttered control and display arrangements. Keys, switches, and control knobs should be sufficiently apart for easy manipulation and placed in a way that reduces the chance of inadvertent activation.
- Ensure that the association between controls and displays is obvious. This facilitates proper identification and reduces the user’s memory load.
- Ensure that the intensity and pitch of auditory signals and the brightness of visual signals allow them to be perceived by users working under real-world conditions.
- Make labels and displays so that they can be easily read from typical viewing angles and distances.
- Use color and shape coding to facilitate the identification of controls and displays. Colors and codes should not conflict with industry conventions.

ECOLOGICAL INTERFACE DESIGN

Ecological interface design (EID) is a conceptual framework developed by Vicente and Rasmussen (1990, 1992) for designing human-machine interfaces for complex systems such as are often found in process-control applications or in computer-based medical equipment. The primary goal of EID is to aid operators, especially knowledge workers, in handling novel or unusual situations. Studies suggest that the use of EID methods can improve operator performance when compared with classical design approaches (Vicente, 2002). The basis for EID is Rasmussen’s (1986) skills-rules-knowledge model of cognitive control, and in this model, critical incidents can result from errors at any of the skills-rules-knowledge levels of human cognition.

The first form of incident includes skill-based errors involving the faulty execution of an otherwise correct plan. Here, behavior is unconscious, nonverbal, and automatic. An example would be inadvertently turning on the wrong switch. Even the most experienced clinicians are prone to skill-based errors as they often occur during highly routine procedures such as in reading a drug label or adjusting a control.

A second category is rule-based errors and involves the failure to apply a rule, such as stopping at a stop sign when driving a car, or not administering a drug to which the patient is allergic. At this level, one step up in Rasmussen’s (1986) cognitive model, people use stored (or precompiled) rules acquired with training or with experience on the job.

Lastly, there are knowledge-based errors in which the initial intention is itself wrong, often due to inadequate knowledge or experience. A clinical example would be administering 10 mg of morphine to an infant. This corresponds to Rasmussen’s (1986) highest cognitive level, and is most suited for unfamiliar environments where prior experience is unavailable to provide a system of rules, such as troubleshooting a new piece of medical equipment for the first time.

Under Rasmussen’s (1986) skills-rules-knowledge model, human behavior moves along a ladder as experience increases. Early on, when one is placed in an unfamiliar environment, problem-solving behavior will be at the knowledge level.
As experience is gained so that rules can be formed, the rules level takes over. In some situations, further experience may lead to even further automation (skills level).

For each of the three cognitive levels, the way in which information and environmental cues are perceived differs. Signals guide skill-based behavior, while symbols apply to knowledge-based behavior. Signals supply time-space information only; they have no meaning at higher levels, and they cannot be verbalized. Signs may trigger rules (stop, start, etc.) or may indicate the state of the system (valve open or closed), but they do not express functional relationships (e.g., the consequences of an open valve). Finally, symbols refer to concepts that support analytical reasoning, such as modeling the system to allow one to determine the consequences of an open valve.

What does all this have to do with avoiding human error when operating complex medical equipment? The answer lies in the following. Rasmussen’s (1986) three levels of cognition can be grouped into two broader categories: (a) analytical-based behavior (knowledge-based behavior) and (b) perceptual-based behavior (rule and skill based). Such a categorization is helpful because perceptual processing has important advantages over analytical-based behavior: Analytical behavior is slow, demanding, and serial in nature, whereas perceptual behavior is fast, effortless, parallel, and less error prone. Thus, the goal of design should be to help people avoid situations requiring them to work at the knowledge-based level, while supporting the use of analytical problem solving for use in unfamiliar situations. And, as emphasized above, design guidelines that match the environment to the people involved is known as ecological interface design.

REFERENCES

**KEY TERMS**

**Cognitive Task Analysis (CTA):** A family of methods and tools for understanding the mental processes central to observable behavior, especially those cognitive processes fundamental to task performance in complex settings. Methods used in CTA may include knowledge elicitation (the process of obtaining information through in-depth interviews and by other means) and knowledge representation (the process of concisely displaying data, depicting relationships, etc.).

**Ecological Interface Design (EID):** A conceptual framework for designing human-machine interfaces for complex systems such as computer-based medical equipment. The primary goal of EID is to aid operators, especially knowledge workers, in handling novel or unanticipated situations.

**Ergonomics:** A synonym for human-factors engineering, especially in the European literature.

**Human-Factors Engineering (HFE):** The branch of engineering devoted to the study of the interactions between humans and systems, especially complex systems, with the goal of designing systems that are safe, comfortable, effective, and easy to use.

**Patient-Controlled Analgesia (PCA):** A computer-based medical technology used to treat severe pain via the self-administration of analgesic agents such as morphine.

**Skills-Rules-Knowledge Model:** A multi-level model of cognitive control developed by Rasmussen that is especially helpful in examining human error and critical incidents.

**User Interface:** The components of a system that the operator uses to interact with that system. For example, in the case of a computer, the operator interacts with it using the monitor, keyboard, mouse, and so forth.
Chapter 2.9
Development Of E-Government Services For Cultural Heritage: Examining the Key Dimensions

Carugati Andrea
Catholic University of Lille, France

Hadzilias Elias
Catholic University of Lille, France

ABSTRACT
This article is aimed at defining a framework for the design of e-government services on cultural heritage. Starting from an analysis of three cases on digitization of different types of cultural objects, we highlight the problems existing in the creation of e-services on cultural heritage. These cases show the existence of four key issues in the development of this kind of information systems: digitization, requirement engineering, standardization, and interoperability. The proposed framework addresses these issues, focusing on the user requirements on one side, and the cultural object representation—which is the key to interoperability—on the other. In the cultural domain, the EU Lisbon strategy pushes for the compatibility of shared content across multiple, locally generated contents. Dynamic content exchange requires the use of a prescriptive framework for the development of cultural heritage Web sites. This article provides such a framework, using observation from concrete applications, knowledge of information systems development methodologies, and the IDEF0 modelling method.

INTRODUCTION
The Lisbon strategy for eEurope (EU Report, 2002) and the following eEurope 2002, eEurope 2005, eEurope 2010, drafted as results of the activities of the European Council, are aimed to “make the European Union the most competitive and dynamic knowledge-based economy with improved economy and social cohesion by 2010.” In concrete terms, this means broadband and high-level Internet-based services for the entire population of the European Union. The means envisioned to achieve this goal are largely based
Development Of E-Government Services For Cultural Heritage

on increasing both demand and offer of e-services respectively, from the public/users and the providers. The problem has been framed as a “chicken and egg” problem and the solution has therefore been to address both ends: increase government-side services and create a friendly legislation for the implementation and sale of broadband connections (EU Report, 2002). This article focuses on the demand side, that is, on the development of the public electronic services.

On the demand side, electronic government initiatives involve providing services in e-government, e-learning, e-health, and e-business (EU Report, 2002). While the efforts of e-government are focusing on providing services to citizens in order to achieve higher efficiencies through automation (tax filing, certification, electronic voting, information provision, and so forth), one other important area of investment regards the facilitation of access to cultural resources. The regional and local cultural heritage (to be defined in a broad sense, from museums to regional gastronomy and folklore) is one of Europe’s greatest economic assets, and ICT and other advanced technologies can dramatically increase the possibility of its exploitation. Until now, the government initiatives for divulging electronic material on the local cultural heritage have been varied in nature and include the creation of portals for information on cultural events, which is the most common model of exploitation today, including the digitization of artwork for archives, the creation of virtual tri-dimensional museum visits with tri-dimensional digitization of art works, and the rendering of archaeological visits in digital formats (Carugati, Hadzilias, & Demoulin, 2005).

Nevertheless, the potential of using electronic services for cultural heritage applications is far from being fully exploited and many initiatives have remained at the stage of pilot projects. Of these pilot projects, few are completed and most contain only one or very few examples of art digitization. Until now, experiences of use of ICT in cultural heritage sectors too often fail in provid-

ing valuable economic results due to a number of problems, and have generated disappointment among the potential players and beneficiaries. The main problems have been:

• In general, at regional and local level, there is shortage of experience and expertise about the use of ICT in cultural heritage areas. Therefore, local and regional administrators have to rely on ICT vendors and consultants, and these in general, are mainly able to suggest general purpose solutions, non-optimised for the specific sector, since even large IT consulting companies have limited expertise in the cultural heritage area.

• If we consider the “conventional” cultural heritage, such as museums and galleries, this sector lacks expertise and experience in marketing and business promotion on electronic media, which makes it difficult to develop credible business models and plans, and to attract investments.

• There are analogous problems also in the cultural tourism sector. There are hundreds of projects and initiatives related to cultural tourism in Europe, but they often have been designed on “supply oriented” thinking, without systematic investigation into what the customer, the “cultural tourist,” is looking for. The issue of user diversity should be considered in the system development process, as pointed out by Klawe and Shneiderman (2005), since it is a critical success factor to steer user preferences. This is valid not only for business purposes, but also and foremost at the community level (Carroll, 2001). Finally, as e-government services are web-based, they are available to different users. Even though the expectations, in terms of services, might differ, Nielsen (2005) states that usability factors influence, for both professionals and other categories, the success of the service.
More generally, the problem of mutual understanding between the cultural sector, service industry, and ICT experts, due to their different ways of thinking, makes it difficult to achieve a fruitful cooperation in areas ranging between education and multimedia production, where the availability of content from the cultural heritage could open very promising development perspectives. In order to be able to develop innovative and marketable products and services with a real cultural added value, the personal direct involvement of experts from the cultural area is absolutely required.

Despite the above-mentioned issues, in Europe as well as elsewhere, there are a number of interesting examples and initiatives, on various scales, of successful economic promotion of the cultural heritage (some of these mentioned above). Unfortunately, they have often only a local or regional visibility, and their positive (and negative) experiences cannot be fully exploited and shared by other projects.

To resolve these issues, the article proposes an integrated framework for developing e-government services on cultural heritage. The framework emerges from the study of multiple cultural heritage electronic initiatives and the in-depth investigation of three case studies. This framework is represented using the activity modelling method IDEF0, where all necessary steps, inputs, outputs, rules, and roles are described in a hierarchical manner.

The article is organized in the following way: first, the research methodology is explained, secondly, we present the case studies and analyse them to highlight key issues, we describe the IDEF0 modelling technique, and then we continue presenting the development framework, focusing on user segmentation and interoperability. Finally, we conclude with a discussion of the proposed framework, highlighting the need for a systemic approach to the activities.

**RESEARCH METHODOLOGY**

The research was carried out following the constructive paradigm of the case study approach (Yin, 2002). In this context, the research used a practice-based lens to identify processes and problems in the development of e-government services on cultural heritage. The process was comprised of three steps:

1. Identify representative cases of e-government cultural services;
2. Identify the different functionalities for the expected users and the problems incurred in these specific cases of information systems development;
3. Propose a way to consider these problems given the constraint of limited resources.

As a first step, we carried out an extensive survey to record most electronic initiatives in the culture domain. The survey identified 142 initiatives, which should cover the bulk of such services for the eight languages spoken by the authors. The languages cover the vast majority of projects in this domain. Among these initiatives, we have selected three that are the most representative because they fit specific criteria that we set out in our research: 1) they continue to exist after the end of the pilot project; 2) they are complete in terms of the cultural content they were supposed to cover; 3) they provide additional functionalities with respect to similar services; 4) they use more advanced technologies; and 5) the informative material about the case was comprehensive.

As a second step, we analyse the three cases in a structured manner looking at a) functionalities provided to the users; b) functionalities provided to other institutions; and c) the development process. These three elements are compared and integrated to indicate key leverage points of these initiatives. In this step, we include usability testing for the two initiatives available online (the
Piero della Francesca Project and the incunabula manuscripts in the Herzog August Library) in order to see if the users find the functions of the Web site friendly and value-adding. For doing this, we carry out the testing with five users, representing different categories (Nielsen and Landauer, 1993). The layout of the testing follows the indication of Molich (1999, p. 109), with a testing room and an observation room. According to the testing protocol, the users were given different tasks to carry out and were required to speak over their actions.

In the third step, we employ the IDEF0 modelling method to describe a high level design framework for implementing e-government services for cultural heritage. The framework expands on treating the key points identified in step two. The proposed solution is therefore the result of deductive reasoning and is prescriptive in nature.

CASE STUDIES

According to the selection process, we consider the following case studies: the Electronic Beowulf Project at the British Library (UK), the Piero della Francesca Project in Arezzo (Italy), and the digitization of the incunabula manuscripts in the Herzog August Library in Cologne (Germany).

Beowulf: The Pioneer Project

The Electronic Beowulf Project represents a pioneering effort in the digitization of cultural heritage. Beowulf is both the first English literary masterpiece and one of the earliest European epics written in the vernacular, or native language, instead of literary Latin. The story survives in one fragile manuscript copied by two scribes near the end of the 10th or the first quarter of the 11th century. Until quite recently, most scholars thought that this surprisingly complex and poignant poem was written in the 8th century or earlier, but Kiernan (1981) stirred up controversy asserting that the work was composed in the 11th century, and that the manuscript itself may have even been the author’s working copy. The manuscript has been damaged over time and the original that is surviving today is in very poor condition (“Why is Beowulf important?”, 2005).

The Electronic Beowulf Project was carried out in the period 1993-1999 in order to digitize the original Beowulf manuscript, of which the original is now in the British Library, and has been made accessible to everyone in electronic format.

Development Process

Since the Beowulf represents one of the first attempts to digitize a cultural heritage object, many difficulties were encountered in different aspects of the project, as the work in preparing the digital edition was very complex in the period considered. Technical difficulties concerned scanning technologies, storing media, and managing the transfer across large distances of large quantities of data or moving 24-bit colour images across different technical platforms. In some cases, it was necessary to devise innovative technical solutions to achieve the desired end result. The following is a quote from Prof. Kiernan’s Web site, highlighting the technical difficulties encountered in 1993:

The equipment we are using to capture the images is the Roche/Kontron ProgRes 3012 digital camera, which can scan any text, from a letter or a word to an entire page, at 2000 x 3000 pixels in 24-bit color. The resulting images at this maximum resolution are enormous, about 21-25 MB, and tax the capabilities of the biggest machines. Three or four images—three or four letters or words if that is what we are scanning—will fill up an 88 MB hard disk, and we have found that no single image of this size can be processed in real time without at least 64 MB of RAM. In our first experiments in June with the camera and its dedicated hardware, we transmitted a half-dozen...
images by phone line from the Conservation Studio of the British Library to the Wenner Gren Imaging Laboratory at the University of Kentucky, where identical hardware was set up to receive the data. Most of these images are now available on the Internet through anonymous ftp or Mosaic ("Electronic Beowulf: A Guide," n.d.)

Besides the technical challenges, there were also issues in the coordination and collaboration of the human resources, due to the variety of disciplines necessary to carry out this task. The domain experts comprised scholars, curators, conservators, photographers, and technical experts (Prescott, 1997), who had to agree on how the activities had to be carried out in order to record the maximum information without damaging the precious document.

In the case of Beowulf, the development was mainly oriented towards the utilization of information technology for capturing cultural content. This activity was not only done to preserve the artifact, but also to enhance the comprehension of the text. From the multiple sources about this project, we can see that, given these requirements, the main activity was to create digital images of the text with different scanning techniques (B&W, 24 bit color, ultraviolet, and high level fiber optic light). This was performed once in order to minimize damage and retain the maximum information digitized because of the extensive erasure and correction in the original manuscript.

The development process followed was a pure waterfall approach (Boehm, 1988). In the situation, the requirements had to be set at the offset of the project and the digitization was done only once per page. Afterwards the content was used to populate a database.

Functionalities for Users

The Electronic Beowulf Project is available to users on CD format that can be purchased from the British Library. The interface provides access to the digital content of a database that contains both pictures and transcribed text. The CD contains multiple transcription of the Beowulf from different accredited authors. Different search criteria are available to query Line (Edition), Folio (Edition), FolioLine (Transcript), Fitt (Edition or Transcript), Scribe (Edition or Transcript). Images can be zoomed to a very high detail in order to be studied by paleographers and calligraphers (see Figure 1). Alternatively, the layout of the screen can show both the original manuscript and the transcription, which is intended to be used by researchers interested in the content of the poem (see Figure 2).

The electronic version enables readers to place the original manuscript’s leaves side by side, to examine the color and texture of the vellum leaves by magnifying the images and to explore the work of the early scribes (see Figure 3). Building on this material, the CD features multiple versions of restoration of which the most recent one was made possible by the different scanning techniques.

Functionalities for Institutions

This project was part of the strategy of the British Library to create the capability to increase access to its collections by use of imaging and network technology. As such, the Beowulf project was not directly geared towards providing content, services, or functionalities to other institutions and remains a stand alone product.

One of the collaborations that emerged from this project was the inclusion of the Thorkelin’s transcript of the Beowulf catalogued in the Royal Library of Copenhagen.

Piero della Francesca: From Restorers to Children

The project of Piero della Francesca regards the digitization of the series of frescos “Leggenda della Vera Croce” situated in the Bacci chapel in the Basilica of St. Francis of Arezzo (Italy). The project was started in the mid 80’s to repair the
Development Of E-Government Services For Cultural Heritage

severe damages that the frescos suffered in the early 80’s. The project was lead by the cultural and artistic heritage authority of Arezzo (Soprintendenza per i Beni Architettonici, Artistici e Storici di Arezzo). The causes of the damage were not clear and therefore the Soprintendenza decided to begin a series of deep and comprehensive scientific and historic research studies to determine the reasons for the fresco’s detrimental conditions. The aim was the preservation of the masterpiece for future generations, and in order to achieve this, it was necessary to find the right technique to restore the painted plaster as well as the building structure itself.

As the project evolved and the restoration work finished, the initial goal was complemented by the creation of a permanent documentation center “for future study and diffusion of information regarding the study and conservation of the mural paintings of Piero della Francesca and to construct, with the use of computer technology, an organic database for the Project and an interactive multimedia system to be hooked up to the international electronic network and available for public consultation.” The project is considered one of the most advanced and demanding efforts of the entire scientific restoration field in Italy and abroad.

Development Process

Originally, this project was carried out to provide professional restorers with new tools for restoring the artworks of Piero della Francesca. For this reason, the initial requirements were set by the restorers and as a result, the quality and detail of the digitized material is very high. For example, they integrated text, vectorial information (CAD
drawing), and raster information (images) which, from a data processing point of view, are of a completely different nature and very complicated. Figure 4 shows the process followed by the project team from preliminary study, to material collection and data processing, and finally the development of software applications.

The four basic activities in this project: data capture, CAD drawing, and raster images (overlaid) are presented in Figure 5.

As in the Beowulf case, the development approach followed the waterfall model. Restorers, together with state institutions, and private and public research institutes, carried out a long preliminary research to set out the requirements. Leading scholars and expert technicians used state of the art information technology to develop the applications that were used to successfully define the restoration approaches to solve the fresco complex problems.

After the end of the restoration work the development continued with the creation of a Web site that used the same collected material from the professional applications, but provided functionalities that were interesting for the wider public. In this second cycle of development, a new set of requirements was created to address the goal of creating a permanent documentation center.

Functionalities for Users

For the restorers, the developed applications provided functionalities to store and search thousands of documents; illustrations of the church choir were compiled in a basic cartographic model and in a variety of thematic mappings with reference to historical studies, visual surveys, diagnostic studies, and scientific analyses and complemented by about 1000 historical/chronological records. The catalogued images could be called up individually from a special menu where they were arranged according to distinct categories. This technology was particularly effective in the phases of correlation, control, and updating of the various studies.
conducted. The images could also be called up from a relational database, which allowed the efficient consultation of records.

Furthermore, the software allowed keeping record of the restoration in process (work site diary, graphs and charts of the work performed, technical specifications, and so forth) as well as adding new cultural content.

To help restorers in their work, the applications operate in the complete respect of the iconographic and technical value of the artist’s work, providing a documentation of the various painting techniques employed by the artist: from the transfer of the preparatory design through the use of stencilled cartoons, etched lines and colored threads, to the application of color to the fresh plaster (a fresco), partially dried plaster (a mezzo fresco), and finally to the dried plaster with special temperas and organic blending agents. A further example of the system’s capabilities is that it provides a chronological reconstruction of the artist’s production. Connected to this, the system allows the study of the relationship between the saline deposits and the presence of fixatives added during earlier restorations or, alternatively, to view the deposits in relation to the various painting techniques used by the artist.

To satisfy the need for rapid consultation in the service of monitoring the state of conservation and the progress of the restoration, system designers developed a thematic glossary with a unified terminology of key words for research and access to the data, organized first in separate technical files and then electronically translated to permit interactive consultation.

Finally, the applications were online with the work site, in order to manage the traditional paper documentation kept by the project director and the restoration technicians and allowing them to have immediate access to and use of the data stored in the system.

In the public Web site, one of the services provided is the classic function of archive. The archive allows searching for historical events by date or by key word and presents the results combining digital images with metadata. The result of one search is presented in Figure 6.

Other interesting functionalities provided are games based on the thematic mappings. The Web site proposes two games: one that consists of adding colours to a black and white painting and the other where parts of the paintings have been divided (electronically) into pieces that the player is supposed to reassemble like a puzzle.

Figure 6. Public archive from the Web site http://www.pierodellafrancesca.it
These two games have an underlying pedagogic reason and would not be possible without the existence of the digitized material specifically created and mapped for the restorers. The Web technologies deployed for this purpose were active images and java applets. An example of the two games is presented in Figures 7 and 8.

**Usability Testing**

The usability testing was carried out by five people: two laymen, one professional restorer, and two children aged seven and eight years old. The adults got the task of finding the painting of “La Madonna del Parto,” starting from the home page. The children had the task of solving the two games. All subjects reported poor navigation between the different pages due to non-existent text explanation of the links and unconventional graphics and structure. Both the laymen and the professional restorer found the painting in approximately three minutes and using 30/32 mouse clicks (against one minute and eight clicks that it would take for an experienced user of the system). The information presented pleased the professional, but not the laymen that reported it as too complex and dull. All three cases showed a critical design error when the user had to pass from the classic Web site view to the database of the art works, because we had to intervene in order to guide the users on how to continue their search.

In consideration of their age, the children were not asked to navigate through the Web site and were presented directly with the games. The

**Figure 7. Puzzle game**

![Puzzle game](image)

**Figure 8. Painting game**

![Painting game](image)
children did not understand what they had to do and also complained that there was no evaluation of their performance. Using the words of the children, these games were reported to be: boring and meaningless.

Despite the interesting use of the digitized material for a wider audience, the outcomes were not value-adding, neither for the laymen nor for the children.

Functionalities for Institutions

The system provides two levels of access to the project material. At the first level, the information is available on the Web site that is hosted by the sponsor of the project (Banca Etruria) and at the second level, which is more complete and contains the full record of the restoration project, the system is available at the offices of the cultural and artistic heritage authority of Arezzo. This local system can be accessed only under official authorization. Data can be processed through a cartographic system based on photogrammetric surveys of the painted walls. The relational database is structured in a series of indexes. Files are divided into didactic, diagnostic, and intervention sections. The local system is addressed to institutions that seek in depth knowledge, not only of the artworks, but also of the restoration process, the mineralogical analysis, and the chemical analysis performed. The left side of Figure 9 shows the local cartographic system and the right frame shows the functionalities for professionals. The green dot indicates the access to the public archive via the Web.

Distributed Digital Incunabula Library: An Architecture for Sharing

The “Distributed Digital Incunabula Library” (inkunabeln.ub.uni-koeln.de/vdib/) is a project aimed at the digitization of all German incunabula. Incunabula, Latin for cradle, are books printed between 1454 and 1500. Worldwide, approximately 550,000 incunabula have been preserved. The Distributed Digital Incunabula Library project was organized as a joint effort of the “Koelner Universitaets und Stadtbibliothek” and the “Herzog August Bibliothek Wolfenbüttel” libraries. The two libraries involved, hold together approximately 5,800 copies incunabula. Out of these, 350,000 pages (approximately 2,000–3,000 titles) were selected for this project, of which 40% were digitized in the first ten months of the two year effort. When completed, the 350,000 pages could represent as much as six percent of the titles of incunabula preserved world wide (Loebbekke and Thaller, 2005).

As a means of achieving global integration while simultaneously keeping institutional in-
dependence, this project proposed as reference architecture a new tool called “Digital Autonomous Cultural Objects (DACOs).” DACOs are characterized by a common behavioral code that provides information about cultural objects on request. The code involves the object wrapping itself in mark-up language. It also provides a persistent addressing scheme, allowing for control of the individual institution holding the good as well as a mapping scheme. Thus, even if the technology (e.g., HTML, XML, SGML, VRML objects, Flash movies, SVG constructions) can be chosen by the individual institution, the structure of basic elements integrated into a DACO is predetermined.

Development Process

In order to deal with the vast amount information to be digitized, a standard development process was followed, which is depicted in Figure 10.

The first stage of the development was the raw digitization of the single pages, which was conducted using a Nikon DXM 1200 and a camera server that stored the images with total capacity of 80 GB. A book cradle for photos in an angle of 45 degrees (see Figure 11) allowed treating the incunabula carefully while simultaneously saving time and money. The pages were scanned in a 24-bit color scheme using a resolution of 3800x3072 pixel leading to a data file size of 34 MB/page. With such a digitization procedure, more than 80% of incunabula were digitized leading to about 12 TB raw data volume.

At the second step, the digitized data was transferred through a local area network to a pre-processing server with 250 GB storage capacity. This server was responsible for the transformation of the output files to the size that is efficient for Web site access and for the different users.

Finally, the files were forwarded to the Web server environment and the digitized files were available on the Internet, after passing a quality control at the Metadata Cache and being transformed to DACOs. These versions of the original files were not more than 10% of the original data size, so that they can be accessed quickly from the Internet. During this phase, the data supervision and the production of the copy-referred development data took place. The archive server offers a storage area for disaster recovery purposes.

The entire architecture was based on cost-efficient Linux servers highly performing for the hierarchical storage organization.

Obviously, beyond tackling the technical challenges, cost played a major role in pushing such
Development Of E-Government Services For Cultural Heritage

...a digitization effort forward. The most important cost factors were:

- Content and subject classification based on the already existing Incunabula Short Title Catalogue (ISTC);
- Workflow/data importation;
- Raw digitization;
- Storage capacity;
- Development and maintenance of the WWW server.

Considering all cost components in this project, the costs for one page amount to roughly 0.75 € (plus metadata and work environment) (Loebbecke and Thaller, 2005).

Functionalities for Users

The users are able to run queries in the incunabula resources in two levels: text-based and image-based. In the former, there are query criteria for locating the page or pages under consideration, containing all metadata and the digitized images. In the latter, there is an image archive with three sublevels of incunabula description: the Incunabula Short Title Catalogue (ISTC) classification, the original image, and the transcription of the image. Furthermore, additional tools are provided allowing for browsing through the manuscripts like in traditional libraries, as shown in Figure 12. A native “dynamic” XML database administers all codicological manuscript descriptions. For some codices, those descriptions amount to the equivalent of fifty printed pages.

There are four different viewing levels of the scanned images suitable for the categories of users who will study the cultural object. Figure 12 shows the query result with the overview level (notice the eye, the glasses, the loop, and the microscope icons above the scanned image). Figure 13 shows a higher level of detail.

Another e-service offered is that the users can download several tools, which measure the performance of typical types of codicological/palaeographic work (e.g., measurement of single characters). As far as available without copyright restrictions, the main scientific literature to work with the codices is also made available in digital form.

Using DACOs, one URL of the library dissolves into about 600,000 URLs of individual...

Figure 12. Query results (http://inkunabeln.ub.uni-koeln.de/ visited on 25/7/05)
references to a specific cultural heritage object that can be referenced directly from any other cultural heritage resource (see, for example, the code \texttt{ig00227000} above the scanned page in Figure 12). This is due to the various views of the metadata and different resolutions.

**Usability Testing**

Given the content of this site, we had to carry out a careful selection of the five users. Finally, we selected three librarians and two history researchers. Even though the test subjects did not research specifically the incunabula, they were selected for their knowledge in the research and management of historical documents. They were given two tasks: to find the document “Mensa philosophica” and the complete production of Gerson. The users completed the first task in less than two minutes and with 10/14 mouse clicks (compared to an experienced user that requires seven mouse clicks). They completed the second task, restarting from the main page, with seven mouse clicks in less than one minute. The users reported the site to be easy to navigate, even though it was in German language. However, they evidenced two major failures in the database operation: the field tables were not linked and the navigation functions in the index, instead of visualizing the records alphabetically, were providing erratic results.

**Functionalities for Institutions**

The highest added value of this project lies in the inter-institutional, cultural content sharing. Cultural heritage brokers, connected to servers recognizing DACOs, integrate many DACOs from different institutions into specialized interfaces, thus serving the interests of laymen and researchers. The communication between the servers takes place via the DACO protocol consisting of several XML-codes transmitted via Hyper Text Transfer Protocol (HTTP). When addressed by a broker, the DACO server describes itself through providing a list of supported “access venues” (e.g., titles, authors, years, and so forth). The access venues can be used by the broker to develop a search mask.

**CASE ANALYSIS**

After examining thoroughly the three case studies of e-services in the cultural sector and with the knowledge of the other existing initiatives, we observed that the greatest challenge lies on the management of four dimensions: digitization,
Development Of E-Government Services For Cultural Heritage

requirement engineering, standardization, and interoperability.

The survey we carried out shows that several European countries are making efforts to comply with the Lisbon strategy and are moving, albeit at different paces, towards the digitization of their cultural heritages. However, given the sheer size of the material, the variety of the applications developed, and approaches taken by the different governments, it appears clear that the seamless integration of the cultural heritages of multiple countries is a very complex task and it is addressed in multiple ways. The three cases showed that digitization is the starting point of these efforts, aiming at the preservation of the cultural content and its availability to a large spectrum of users. All three cases show a very similar approach to the digitization problem, using various scanning technologies to create digital facsimile of cultural objects.

The second dimension concerns the requirement engineering. In the three cases observed, the requirements were set initially by the most demanding groups, namely the professionals working with cultural objects in their daily working life. Researchers were in contact with the technical developers in order to discuss and define the initial set of requirements. This helped to set very high quality standard for what later became material available to laymen. The process of creating the Web sites available to the public was carried out following a top down approach that provided the digitized content to the public without examining the specific needs of the different categories of users. A notable exception is the functionality offered in the Piero della Francesca project where the pedagogic games addressed the needs of the specific target group of children. However, this effort followed the same push strategy as the other two and our usability tests proved the limitation of this approach.

As far as standardization is concerned, there seems to be a trend towards finding a common way

to represent cultural objects. In the early cases, the standardization regarded the format of the digitized images (e.g., jpg, tiff, bmp formats). Instead, the incunabula project shows a more structured approach to the standardization problem, using the DACOs where, not only the images, but also the metadata, follow a specific standard.

Finally, we have also observed an evolution towards higher interoperability of cultural information systems. The early example of the Beowulf was designed as a stand alone project and it is only available to users on CD-ROM to be bought from the British Library. The Piero della Francesca project started as an independent solution for professionals, but it was later made available on the Web with some of the original functionalities activated. The incunabula project was—from the offset—born as a Web-based information system to execute queries on the pages of digital incunabula. This last effort is directly geared towards making the material and the tools available to other cultural Web sites. In order to increase the interoperability of existing or future applications, there should be distributed, localized development of content that can be integrated as it is created. The summary of the case analysis is shown in Table 1.

In an era where content exchange is becoming the norm, and access to cultural content is mandate by law (eEurope strategy), it becomes paramount for the different governments to develop their content, respecting a framework that will allow different Web sites to freely exchange content. The framework will have to address the four dimensions just described and embed them into a process of information system development. The development of such a framework will be the focus of the next part of the article, beginning with the description of the modelling technique used—IDEF0.

**IDEF0: THE MODELLING TECHNIQUE**

In order to model our framework, we selected a modelling technique that was suitable for easily conveying a message and, at the same time, did not impose methods or techniques on the system modelled. Among the possible techniques (e.g., Data Flow Diagram, ARIS, UML, and so forth), we have selected IDEF0 for its simplicity, well knowing that experts easily translate it into any other modelling tool.

The IDEF0 modelling technique is intended to model the decisions, actions, and activities of a system. It is not only the most widely used, but also the most field proven function modelling method for analysing and communicating the functional perspective of a system (Malhotra and Jayaraman, 1992). IDEF0 was derived from a well-established graphical language, the Structured Analysis and Design Technique—SADT (Marca and McGowan, 1988). The IDEF0 modelling method establishes the scope of analysis either for a particular functional analysis or for future analyses from another perspective. As a communication tool, IDEF0 enhances domain expert involvement and consensus decision-making through simplified graphical devices. As an analysis tool, IDEF0 supports the identification of the functions performed and what is needed to perform them.

The basic activity element of an IDEF0 model diagram is represented by a simple syntax. A verb-based label placed in a box describes each activity. Inputs (I) are shown as arrows entering the left side of the activity box, while the outputs (O) are shown as exiting arrows on the right side of the box. Controls (O) are displayed as arrows entering the top of the box and mechanisms (M) are displayed as arrows entering from the bottom of the box. Inputs, Controls, Outputs and Mechanisms (ICOMs) are all referred to as concept. An IDEF0 model diagram is
Development Of E-Government Services For Cultural Heritage

then composed of several activity boxes and related concepts to capture the overall activity. IDEF0 does not only capture the individual activities, but also reveals the relationships among activities through the activities’ related concepts. For example, the output of one activity may become the input, control, or even a mechanism of another activity within the same model.

A strategy for organising the development of IDEF0 models is the notion of hierarchical decomposition of activities (see Figure 14). A box in an IDEF0 model represents the boundaries of an activity. Inside that box is the breakdown of that activity into smaller activities (child diagrams), which together comprise the box at the higher level (the parent). This hierarchical structure helps the analyst keep the scope of the model within the boundaries represented by the decomposition of the activity. This organisation strategy is also useful for hiding unnecessary complexity from view until a more in-depth understanding is required.

One of the most important features of IDEF0 as a modelling concept is that it gradually introduces

Figure 14. Hierarchical decomposition of an IDEF0 model diagram
greater and greater levels of detail, through the diagram structure comprising the model. In this way, communication is enhanced by providing the reader with a well-bounded topic with a manageable amount of detail to learn from each diagram. The decomposition is graphically indicated with codes; the highest level is called A0, and the activities which are included are indicated with A1, A2, A3, and so forth. (see Figure 14).

An IDEF0 model starts by presenting the whole subject as a single unit—a box with external-arrow boundary conditions connecting it to functions and resources outside the subject. The single box is called the “top box” of the model or the context diagram. Since the single top box of an IDEF0 model represents the subject as a whole, the descriptive name in the box is general. The same is true of the external arrows of the model, since they represent the complete set of external boundary conditions of the subject as a whole, including access to mechanism support that supplies additional means of performance.

Description of the Proposed Framework

Based on the analysis of the cases, the exhaustive survey of the cultural heritage initiatives, and our theoretical and practical knowledge on information systems development, we propose a framework for the development of e-services for cultural heritage based on four ideas:

1. E-services for cultural heritage are, in essence, information systems. As such, existing methodologies can be adopted and adapted for their development.
2. IDEF0 is a proven modelling technique for the development activities of information systems.
3. The impact of Web sites for cultural heritage increases with the enhancement of content integration from multiple sites: a one-stop cultural heritage site can be imagined as the ideal goal and therefore compatibility of the finished local products is paramount.
4. Multiple types of public have to be served by these sites; satisfying each group is important to serve the goal of increasing demand for services in the eEurope strategy.

According to these four ideas and the four dimensions identified in the analysis, we developed a framework which contains the following five phases: collection of user requirements, digitization of cultural content, system interoperability design, cultural content organization, and e-government cultural portal development. These phases are expressed as activities in the IDEF0 model of Figure 15.

The mechanisms that we have identified are:

- Users. This mechanism includes art specialists (like the restorers in the Piero della Francesca case), historians, researchers, and the public in general. In Figure 15, it is shown that the mechanism “users (M1)” supports the collection of users’ requirements (A1), the organization of cultural content (A4), and the development of e-service (A5). The participation of users in these activities ensures the user-centered evaluation that the usability testing proved essential to avoid critical errors.
- Technical project team. It includes the project manager, the system architects, the system analysts, the database designers, and the developers, including the Web designers. In figure 15, it is shown that the mechanism “technical project team (M2)” supports the collection of users’ requirements (A1), the organization of cultural content (A4), and the development of e-service (A5). The participation of the technical project team in these activities ensures that the users’ needs can be supported by the technology and the resources available.
The cultural organization. It includes all the experts in the specific art works that are part of the cultural heritage e-service (curators, conservation scientists, archivists, museum technicians). This mechanism is discrete from the users because they provide information about the art works and are not necessarily using the service. The participation of the cultural organization in these activities ensures that the art work will be treated in the proper way, that the needs of other cultural organizations, in terms of exchange of the digitized materials, are upheld, and that the metadata is correct and complete.

The specific characteristics of each activity are presented in detail in the following sections.

**Collection of User Requirements**

This activity is aimed at the creation of the requirements document for the development of the e-service. To design an efficient cultural heritage e-service that meets the public needs, it is first of all necessary to define the target group users and understand the requirements that have to be addressed. The survey of the cultural heritage initiatives highlighted different groups of users. One classification (see Dipartimento dei Beni Culturali, Italy) identified users as internal, private (customer market), or corporate (business market). For example, the internal public might be the law enforcement agencies accessing the artwork database for research on fakes or stolen material. The differentiation between private and corporate is quite unusual in a governmental service, since every citizen should be equal in front of the state. This might be the indication of a trend to adopt models from e-commerce into
Development Of E-Government Services For Cultural Heritage

e-government, or it might be the result of using technology providers used to dealing with the private sector instead of with the government. The three cases analysed above show that segmentation is deemed important by the creators of cultural heritage e-services.

The input of this activity is a plan for the creation of an e-service for cultural heritage. The plan may originate from a specific need like in the case of Piero della Francesca, from a research interest like in the Beowulf case, or from a long term plan for the distribution of content like in the incunabula project.

User segmentation (Control C1 in Figure 15) guides how the requirements will be created. The users can be classified according to their profession, location, affiliation, age, and interests (Sen, Padmanabhan and Tuzhilin, 1998). Region and language can be used to make sure that the service provided is culturally acceptable and the language is understandable by the audience. Among demographical variables, age may be useful to present cultural heritage accurately at every group age. Occupation or community of practice of the user is a strong determinant of the requirements for the e-service.

As these services are rather new, it is difficult to fathom what would be the requirements of the different groups. Therefore, it is important to develop prototypes for the requirement definition. The user-centered evaluation, following the testing protocols of Nielsen and Landauer (1993) and Molich (1999), should be carried out to assure that the technical project team has well interpreted the user requirements. The testing protocol is represented by the control C2 in Figure 15.

If the information is missing because the service is new than the cases indicate that it is convenient to serve the most demanding group first, like the restorers in the Piero della Francesca case, and then reduce the complexity as other user segments are identified.

The groups involved in this activity are the e-service project team (the technical developers), the cultural organization that owns or manages the art works, and the users in their different declinations. The users are necessary because they will be able to state what the needs are. Users should be representative of the categories identified in the segmentation exercise. The technical team is necessary because of the preparation for the technical work ahead. They have to make sure that the requirements can be technically satisfied. Finally the cultural organization is also necessary because they know how the art works can be handled and what are the aspects of their digitization that are most valuable to cover. As an example, the case of the Beowulf showed that it was necessary to do the scanning under UV light and only specialists could point that out.

Despite a careful segmentation, the actual collection of the requirements can result in a quite challenging process. Most constituencies, especially layman, will in fact be unaware of what they want, since innovative e-services are still very limited. While the mental model of a museum or an archaeological visit is shared among people of different countries, there might be requirements that no user can state, simply because one cannot ask what is not known. For the elicitation of requirements from the final users, it would then seem appropriate to engage with the different constituencies in an iterative process using prototypes of interfaces. This prototype-based requirement elicitation should be done autonomously from the setting of the requirements for the content digitization, where the use of an agreed upon standard is required.

The output of this activity is the requirement document. For the technical project team, it will contain the functional specification of the e-service to be developed. For the cultural organization, it will contain the specification for the preparation of the art works and the specifications for the descriptions to be prepared.
Digitization of Cultural Content

This is the activity of digitization of cultural content. The reasons for digitization, or more precisely for the digital conversion of non-digital cultural source material, are varied and may well overlap. The decision to digitize has the following objectives:

- To increase access: this is the most obvious and primary reason, where a high demand from users is estimated and the administration has the desire to improve public access to a specific collection.
- To improve services to an expanding user’s group by providing enhanced access to the institution’s resources with respect to education and long life learning.
- To reduce the handling and use of fragile or heavily used original material and create a backup copy for endangered material such as brittle books or documents.
- To give the administration opportunities for the development of its technical infrastructure and staff skill capacity.
- To develop collaborative resources, sharing partnerships with other administrations to create virtual collections and increase worldwide access of a country’s heritage.
- To seek partnerships with other administrations to capitalize on the economic advantages of a shared approach.
- To take advantage of financial opportunities, for example the likelihood of securing funding to implement a program, or of a particular project being able to generate significant income.

According to which of these needs are deemed more important, the requirement document is taken from the previous activity and transformed into two outputs: the digital facsimile and a new systems specification document revised after the digitization. The technical project team and the cultural organization collaborate in this activity which, as seen in all three cases, is very demanding.

The control is provided by the MINERVA guidelines. MINERVA, MInisterial NEtwoRk for Valorising Activities in digitization (http://www.minervaeurope.org/), is a resource for guidelines concerning the digitization of cultural content. MINERVA was created by a network of European Union (EU) Member States’ Ministries to discuss, correlate, and harmonize activities carried out in digitization of cultural and scientific content for creating an agreed European common platform, recommendations, and guidelines about digitization, metadata, long-term accessibility, and preservation. Due to the high level of commitment assured by the involvement of EU governments, it aims to coordinate national programs, and its approach is strongly based on the principle of embeddedness in national digitization activities. The use of the MINERVA guidelines insures the contacts with other European countries, international organizations, associations, networks, international and national projects involved in this sector.

The output of this activity is the digitized content. This content can exist independently from the creation of the e-service that uses it (like a repository) or will be used in the development activity. The other output is the revised version of the specification document in accordance to the problems and opportunities that the digitization phase might bring to the surface.

System Interoperability Design

This activity is aimed at assuring the compatibility of the content generated across e-services. This activity takes as input the systems specifications produced during digitization and adjusts them for interoperability.

For this activity, we propose as control the adoption of the ISO 21127 standard (http://www.iso.org/). ISO 21127 is a domain ontology for
cultural heritage information. As such, it is designed to be explanatory and extensible, rather than prescriptive and restrictive. Currently, no specific formalism for semantic models has been widely accepted as standard, which is proven by the existence of the DACO used in the incunabula case. However, the semantic deviations between the various available models are minimal. At this stage, we prefer to recommend the use of ISO 21127 instead of the DACO as control, since the DACOs are not recognised as a standard yet.

The ISO standard has been formulated as an object-oriented semantic model, which can easily be converted into other object-oriented models. This presentation format will be both natural and expressive for domain experts, and easily converted to other machine readable formats, such as RDF (Resource Description Framework) and XML. Considerable effort has gone into achieving these goals; all cross-references and inheritance of properties, for example, are explicitly resolved. This has led to a certain degree of redundancy, but makes the document more readily comprehensible and facilitates its use as a reference document.

The standard is intended to cover all concepts relevant to cultural heritage information, but most particularly, those needed for wide area data exchange between museums, libraries, and archives. Due to the diversity of the subject matter and the nature of cultural heritage collections, this goal can be achieved only by extensions to the standard. However, thanks to its object-oriented nature, the ontology offers a backbone of powerful general concepts, which have a wide application.

The primary purpose of ISO 21127 is to offer a conceptual basis for the mediation of information between cultural heritage organizations such as museums, libraries, and archives. The standard aims to provide a common reference point against which divergent and incompatible sources of information can be compared and, ultimately, harmonized.

The mechanisms involved are the cultural organization and the technical project team. The reason why this cooperation is required is that this activity is both technical—it will shape the technical development of the e-service—but is also highly connected to the conservation practices. Only the experts in the management of the cultural content can, in fact, specify how and what parts of the content would need to be shared.

The output of this activity is the systems specification document, enriched with the information about interoperability.

**Cultural Content Organization**

In this activity, the content is organized. In particular, the cultural organization (the mechanism) takes care of creating the descriptive data about the digitized material: the metadata. The description is based on the specification document and takes into consideration the interoperability needs specified in the previous activities.

The specific activities that we have identified in our survey of existing e-services are the following:

- Primary data registration and description of cultural objects. This data refers to basic identification information, classification, physical shape, condition, geographical location, construction date, application, properties, and relation with other objects.
- Collection of the administrative information concerning the relevant collection and monument management. This information is the prerequisite for the management and documentation of monuments or objects, which are part of a museum collection.
- Documentation of digital products and processes. The meta-data that concern the processes of digitization, identification, quality and thematic content of the digitized material belong to this category.
- Preservation information of the cultural content. This information refers to meta-
data for the long-term preservation of the digitized material.

- Publishing data of the cultural content. The digitized material is published on the Internet and is also stored in optical technology media (CD-ROMs, DVDs). The data included in this category aims at the educational use of the cultural digitized material and the effective creation of multilingual versions.

Considering these activities, and the specification document we recommend, as control, the use of the ICOM/CIDOC standards (Abraham & Means, 2001; Aquarelle, 1999; Baskerville & Pries-Heje, 2004). The ICOM/CIDOC standards are the output of a joint effort across museums, archaeological sites, and other cultural initiatives to create internationally accepted guidelines for museum object information. Since the ICOM/CIDOC standards have been agreed by the cultural organizations, their use should be straightforward.

The output of this activity is the final requirement document containing functional, structural, and process specifications.

**E-Service Development**

Once the requirements have been collected, the material digitized, and the standards set, the time for the actual e-service development arrives. We envision the e-service to be, as a starting point, of the kind presented in the incunabula project: a complete, widely accessible, shared content of precious cultural material.

The e-service development can be regarded as a problem of information system development. In the particular case of cultural heritage e-services, there are particular conditions that make them different in relation to the needs of traditional Web sites treated in the literature (Baskerville and Pries-Heje, 2004). The needs for quick adaptability and flexibility (ibid) do not apply in most cultural heritage cases where the data is stable and the user interfaces are also quite stable in time. The presentation of the artworks is also quite stable in time and it has achieved an agreed upon format. Furthermore, the digitization might involve very fragile artworks, besides being very complex and time consuming, and therefore, it cannot be envisaged that the basic data coming from digitization can be recreated multiple times.

Therefore, the development should not focus on rapid and continuous development, but rather, comply with the more traditional system development lifecycle, focusing on long term usage: efficiency, reliability, low cost maintenance, and robust functionalities (Truex, Baskerville, and Klein, 1999). However, given that most e-services will be Web-based, some of the characteristics of Web sites can be used advantageously in cultural heritage services. The interface must be particularly cured as visitors are varied in age and education; therefore, particular attention to usability must be taken. Furthermore, standards must be strictly respected as presented previously, since data might and should be used in multiple sites or in multiple ways in the same site. Being prepared to provide multiple views of the same digitized material will be a critical factor for the success of cultural heritage e-services over time because the development of views and interfaces will demand much less work compared to the digitization of content. Finally, particular attention should be posed to scalability of e-services, given the staggering quantity of material potentially available for display.

Our case and our survey show, for most e-services, the first user group to be served are professionals. Serving professionals—with high requirements on the quality of the digitization and on the metadata—are a very good starting point because, for the reasons connect to the aforementioned material, it is easier to simplify a high-quality digitization, rather than re-digitize to add information.

Therefore, we envision at least a double loop development where, in a first instance, the
Development Of E-Government Services For Cultural Heritage

cultural organizations and the professionals are served. Once professional e-services are created, then a second loop of development can be carried out where other services are added for the wider public. The first loop uses as mechanism the technical team, the cultural organization, and the professional users. The second loop uses the technical team and representatives of the public as mechanisms in the first activity.

The control proposed for this activity is the ISO 9126 standard, which is concerned primarily with the definition of quality characteristics to be used in the evaluation of software products. Using this standard as control should assure the quality of the e-service.

The output of this activity is one or multiple e-services.

REFLECTION ON THE FRAMEWORK AND ISD METHODOLOGIES

At first sight, the framework resembles a variation of the waterfall methodology for information system development. This impression is undoubtedly strengthened by the fact that the e-services for cultural heritage are indeed information systems. However, the framework proposed in Figure 15 does not propose a waterfall-like development, but rather, shows the activities involved with their inputs, controls, mechanisms, and outputs. The framework does not specify the sequence of the activities, even though visually it might seem so. The fact that the activities are depicted in Figure 15 from the top left to the bottom right follows simply a tradition in IDEF0 modelling.

In fact, in real cases, the activities might go on in parallel or even be carried out in different moments. Typically such an e-service can use material digitized long before the project is started or, even more commonly, can use descriptions (metadata) created before the project is started. The framework (as it does not specify a sequence) can be adopted in any ISD methodology and will still be able to provide indications for what to do, following which rules, who has to do what, and what input has to be used.

The order in which the activities are actually carried out, during the project of e-service development, should be decided contextually by the actors involved. Our research has pointed out the importance of user involvement, where users are not only professionals, but also and foremost, laymen. Appealing to the wider laymen category will, in fact, ensure the long term interest in the e-service. Therefore, the use of a process that contains iterations based on user testing is highly recommended and the framework will guide the choice for inputs, outputs, controls, and mechanisms for each activity in the multiple iterations.

CONCLUSION

The study of the existing initiatives of e-government on cultural heritage shows that the different member states are pursuing the Lisbon strategy for eEurope, but in different ways and at different paces. While some countries are more advanced than others, even for the leading ones, it is difficult to speak about concerted action to create a one-stop site for cultural heritage being this at subject level (archaeology, graphical art, sculptures, and so forth), local level, national level, or international level. While cooperation obviously exists among museums, ministries, universities, and other institutions, this cooperation only very recently has begun to be addressed seriously. While cultural organizations, research institutions, and standard organizations have begun to create usable standards, one of the main issues that we have observed in an initial survey is the lack of a methodology that systematically integrates and adopts these standards.

The in depth examination of three case studies of e-services has pointed out four dimensions that are important to address when developing these
Development Of E-Government Services For Cultural Heritage

services: digitization, requirements engineering, standardization, and interoperability.

These dimensions have been linked to the existing standards to create a development framework, which addresses both practical issues and future needs.

In our view, the problem of advancement in the cataloguing and divulgence of electronic material does not reside in technology, but in organizational traditions and cultures that, knowingly or unknowingly, might be retarding the process, and in the recognition that electronic cataloguing and presentation of artwork is not locally limited (e.g., at museum or site). Politicians and administrators need to understand that to achieve the goals of eEurope, cultural heritage needs to move from the physical place to the electronic space. We believe that this article provides a solid framework to achieve this goal. The proposed framework is easy to understand: based on IDEF0, clear in its content and in the definition of what is needed, who is needed, what rules apply, and what are the goals for each activity. It provides, to the willing and open-minded team, the right guidance (without being restrictive) towards the development of e-services for cultural heritage that are not only effective upon completion for a specific location, but that will stay effective in the future and without borders, if the standards for interoperability are respected.

This framework should be further examined in an action research environment where not only the framework should be put into use but the organizational conditions that characterize this type of projects could be studied, as well. This will allow us not only to validate the framework but also to study the condition under which the “cultural heritage e-service plan” (the primary input of the framework) is actually made.

ABSTRACT

This chapter proposes an activity-oriented approach to digital television (DTV) user interface design. Our approach addresses DTV usefulness and usability issues and entails two phases. A user activity analysis is conducted in phase one, and activities and their social/cultural context are identified. DTV service functions are then conceived to support user activities and their context. DTV service usefulness can be ensured as a result. The user interface design considers both activity requirements and user requirements such as user’s related product experience, mental model, and preferences in phase two. Consequently, DTV usability is achieved. A DTV user interface concept is thus proposed. The interface design concept contains the following design features: activity-oriented user interface flow, remote control for universal access, shallow menu hierarchy, display management, adaptive information presentation, and context sensitive functions. Usability evaluation results indicate that the user interface is easy to use to all participants.

INTRODUCTION

DTV has several advantages over conventional analogue television: better picture and sound quality, more channels, interactivity, and accessibility.
Many countries plan to switch to DTV within the next 5 to 10 years. To facilitate DTV user adoption, Hsu (2005) conducted a survey exploring factors driving DTV diffusion. Identified factors were: government support, reliable technology, price, DTV service usefulness, and easy-to-use user interface. Service usefulness and easy-to-use user interface were among the most important driving factors determining user adoption.

Identifying useful services and designing an easy-to-use user interface is challenging. First, DTV can be complicated for most users. After switching from analogue to digital, television is no longer just a standalone audio-video device. DTV is becoming central to the digital home by providing information services; controlling home appliances and security devices; supporting communication activities; performing business transactions; storing video images; and so on. Therefore, users’ manipulation of numerous service applications and easily accessing what they want is critical. Secondly, nearly everyone may use DTV. However, different users may use DTV services for their own purposes and have different usage patterns. Moreover, users interacting with the system have different experiences and abilities. Therefore, accommodating diversified user needs and skill levels is also important.

The user-centered design (Norman & Draper, 1986) has been a dominant approach to user interface design in meeting usability requirements. The user-centered design approach essentially focuses on and includes the user in the design process, beginning with user identification and user tasks. User’s target-market characteristics are identified according to user analysis. These characteristics include: demographic characteristics, knowledge and skills, limitations, attitude, and preferences. Based on these characteristics, product requirements can be determined. Task analysis identifies user needs in task performance. These needs include functions and information as well as control, enabling users to perform tasks. Task analysis results are used to specify functional and use requirements. The user interface considers compatibility between user’s information processing limitations and task demands, to ensure usability. Since the user-centered approach recognizes that the design will not be right the first time, it suggests that an iterative design be incorporated into the product development process. By using a product prototype, the design can be refined according to user feedback. The user-centered design approach has been successfully applied to many computer products.

However, the user-centered approach has some drawbacks and limitations. Norman (2005) warned against using it in designing everyday products. He argued that the user-centered approach provides a limited design view. It is suitable for products targeted for a particular market and for specific user-task support, but everyday products are designed for everyone and support a variety of tasks. These tasks are typically coordinated and integrated into higher-level activity units. For everyday product design, Norman proposed an activity-oriented design approach. He asserted that a higher-level activity focus enables designers to take a broader view, yielding an activity-supportive design. In a nutshell, the activity-oriented approach focuses on user activity understanding, and its design fits activity requirements.

In line with Norman’s (2005) notion of activity-centered design, Kuutti (1996) proposed an activity theory application framework to the human-computer interaction design (HCI). According to activity theory (Engeström, 1987), an activity is the way a subject acts toward an object. An activity may vary as the object changes, and the relationship between the subject and object is tool mediated. Tools enable the subject to transform an object into an outcome. Furthermore, an activity is conducted in an environment that has social and cultural context. Two new relationships (subject-community and community-object) were added to the subject-object model. The community is a shareholder group in a particular activity or those who share the same activity objective. Rules and
regulations govern how an activity is carried out
in a community and impose environmental influ-
ences and conditions on an activity. Furthermore,
community members assume different activity
roles and responsibilities. These components
provide a social contextual framework for HCI
design. Therefore, activity theory not only focuses
on user activity analysis, but also considers coop-
 erative work and social relationship interactions
(Kuutti, 1996). That is, activity theory treats
HCI as a complete interaction perspective, not
limited to interaction between an individual and
a computer.

Although several researchers (e.g., Bødker,
1996; Nardi, 1996) have attempted to apply ac-
tivity theory to HCI design, there is no formal
method for putting activity theory into practice.
To resolve this problem, Mwanza (2002) proposed
a systematic design framework called activity-
oriented design method (AODM), based on the
activity triangle model (Engeström, 1987). The
method contains eight steps aimed at successively
collecting information regarding eight activity
components: Subjects, objects, tool, rules, com-
munity, division of labor, transformation process
and outcomes. Mwanza successfully applied
activity theory to two projects by employing this
eight-step model.

DTV is intended for individual use in daily
life activities. A life activity can include many
others (family members, friends, or others) be-
sides the individual, and may include many social
processes. Therefore, DTV can be a social device
shared by family and friends alike. DTV design
should consider social and cultural contexts.
Furthermore, life activities are dynamic. They are
composed of task sets that change as conditions
change. Thus, the design should reflect possible
actions and conditions in which people function
(Norman, 2005).

This chapter proposes an activity-oriented
approach to DTV user interface design. This
approach begins with an understanding of life
activities and their requirements in use context.
Activity theory is used as a framework for life
activity understanding. Life activities are treated
as analysis units. Analysis on use context includes
interaction among community members under-
lying the activity, rules governing the activity,
and physical, as well as sociocultural aspects
of the use environment. From activity analysis,
activity requirements are determined and, in
turn, functional requirements can be specified.
After activity requirements are determined, the
approach moves to identifying user requirements
such as users’ experiences, skills, knowledge,
and preferences. User interface design tries to
optimize compatibility between an activity and
its contextual elements so that it not only meets
activity requirements, but also satisfies individual
as well as social needs. In so doing, DTV useful-
ness and usability can be ensured.

The proposed activity-oriented approach
consists of four steps:

- **Analyze DTV activity requirements.** People engage in an activity in order to
attain an objective. The objective is then
transformed into an outcome that motivates
people to engage in the activity. Accordingly,
the activity can be identified by the motive
for using DTV. Since the identified activities
may be too numerous, related activities are
grouped into activity groups for simplic-
ity.

The intertwined relationships among ac-
tivity components in each activity group
are analyzed. All members and their roles
in the underlying activity are identified.
Moreover, rules governing DTV use and the
social processes underlying the activity are
analyzed. Social and cultural issues related
to DTV use are identified. Activity models
are then constructed to depict relationships
between the eight activity components.

- **Envision services to support each activity
group.** By analyzing activity requirements
and its social context, appropriate applica-

tion services and contents are envisioned. The envisioning process is based on activity models constructed in the previous stage. Conceptual scenarios developed describe how the conceived services support user activity. A DTV system conceptual model is then developed describing system services, their attributes, and the relationships between services. The DTV system can then smoothly meet activity requirements and prove useful to users as a result.

- **Establish a use model.** A use model delineates how users will use DTV services to carry out their activity. Use model development begins with detailed activity analysis. An activity has a hierarchical structure containing a coordinated, integrated set of actions. Actions are targeted toward a specific goal and are achieved through operations. Conditions will control what operations will be taken, and conditions and goals together will determine tool use. Based on the activity-actions-operations hierarchy and activity flow pattern, a use model is then developed to describe the mapping between DTV services and activity flow. This mapping is used as a basis to determine user interface structure and components.

- **Understand user requirements.** To achieve usability goal, user interface design must consider user characteristics. User characteristic exploration includes two parts: (1) understanding users’ previous experiences, and (2) exploring users’ mental models and preferences for interaction methods. Users accumulate previous experience from earlier product interaction. Previous experience contains users’ knowledge, skills, mental models, and affective responses to the related products. Leveraging users’ previous related product experiences can ease users’ new product learning and prevent user frustration. Furthermore, users interact with the system based on their system knowledge that is, their mental models. Designing a user interface compatible with a user’s mental model enhances product usability. Interaction method preference affects users’ product attitude. User interface design must meet these user requirements to enhance usability and increase user acceptance.

**CASE STUDY: A DTV USER INTERFACE DESIGN**

Several qualitative and quantitative methods employed in this study applied the activity-oriented approach. Qualitative methods include ethnographic research, in-depth interviews, and a focus group. These qualitative methods analyze activities and their social/cultural context and conceive DTV services. Quantitative methods were also conducted, assessing activity importance and collecting user characteristic information. A survey was conducted to meet the purpose. The survey comprised of questions regarding user activities; services and contents needs; user experiences with related products; user expectations of user interface style; and user characteristics such as demographic variables and attitudes toward technology adoption. The one thousand questionnaire-sampling scheme—distributed across Taiwan—proportionately represented the Taiwanese population in terms of age, sex, occupation, and geographical location. Of the returned questionnaires, 960 were valid.

**Understanding User Activities and Their Context**

Ethnographic research conducted observed current life activity practices. Twelve lead users (Rogers, 1995) participated in the research. Observations focused on activities engaged in; when and where they were engaged in; how the activity was carried out; who took part in the activity and their roles; and what rules governed this activity.
Observers tried to piece information together using the activity triangle model (Engeström, 1987). In some cases, observation results were insufficient to provide a whole activity system picture. Thus, in-depth interviews conducted collected supplementary information. Through ethnographic research and in-depth interviews, 34 life activities were identified and their activity models obtained.

These activities then served as a candidate activity list in the survey questionnaire. Survey respondents were asked to rate the importance and frequency of activity performance. Exploratory factor analysis conducted explored the interrelationships of 37 activities. A Kaiser-Meyer-Olkin (KMO) test of sampling adequacy obtained a good value of 0.911, the Bartlett’s test of Sphericity was significant (p <0.001), and the matrix determinant was in acceptable range. Factor analysis results determined five activity groups (refer to appendix A): (1) entertainment (9 activities), (2) information (6 activities), (3) education (9 activities), (4) transactions (5 activities), and (5) daily living (5 activities).

Identifying DTV Service Needs to Support each Activity Group

A focus group meeting met to envision potential DTV services and contents to support each activity group. The focus group consisted of two DTV R&D engineers and six lead users with DTV experience in other countries. The meeting began with a briefing on the latest DTV technology and service developments by the two R&D engineers. Next, lead users were given the activity model obtained in the earlier stage and asked to brainstorm potential DTV services that would be useful in supporting each activity group. Thirty-seven candidate DTV services and contents were gathered as a result. After identifying potential services, conceptual scenarios were developed, describing service use in carrying out activities.

These 37 candidate DTV services were then included in the survey questionnaire. Respondents in the survey rated the services/contents in terms of their usefulness in supporting life activities. Useful services for each activity group are shown in Table 1. Some services/contents were considered useful in supporting more than one activity group.

Developing a DTV use Model

The second ethnographic research conducted collected detailed activity analysis information to determine identified service and content functional requirements in each activity group. Five families were recruited for the ethnographic research. These families were lead users of 3C products. The research took place on one weekday and one weekend. Observations were made to learn how life activities are performed in the family context and how each family member

520
took part in the activities. Observation results gathered decomposed activities into action and operation levels. Moreover, in-depth interviews requested interviewees to envision how they would use DTV services and contents to support their activities. Use models were then developed based on interview results. These use models served as a basis for determining user interface components and its structure.

Ethnographic research results indicated that each activity group had its own specific use model. For example, entertainment activities are performed in a sequential manner. After users find the right program, they will watch the program for a while before they move onto the next activity. Therefore, a sequential menu structure is appropriate to support this type of activity. On the contrary, an information-searching activity is an iterative process. Users navigate through information space in order to seek for related information. Users may easily get lost and find it difficult to return to their original location. Therefore, a network structure is suitable for this type of activity.

ANALYZING USER REQUIREMENTS

Understanding User Experience

Survey respondents rated past experience with related products in terms of ease of use and frequency of use. The ease-of-use score reflects product usability and the frequency-of-use score indicates activity support usefulness. Combining the two scores yielded a good experience index for each product. Results showed that nine multimedia products, four information products, and two communication products were rated as “good experience products.” Among these products, respondents with high interaction skill rated television sets, TV games, and personal computer as the top three “good experience products,” whereas television sets and TV games were regarded as “good experience products” by respondents with low interaction skill.

Identifying UI Design Features

In-depth interviews conducted identified design features that contribute to good experience. Eight persons participated in the in-depth interview sessions, including two businessmen, two children, two housewives, and two older adults. They were frequent users of “good experience products.” In the interviews, participants were asked to describe their interaction experience with TV sets, TV games, and personal computers and then list design features they considered good.

Good design features for TV sets were: (1) control function visibility—all control functions have dedicated physical keys easily located on the remote control; (2) shallow menu hierarchy—most TV menu options are organized in one or two levels. Too many menu layers confuse and disorient users so that they have difficulty reaching the target option; (3) feedback information visibility—TV provides immediate selection and system response feedback. Selection feedback shows immediate user selection. System response feedback provides the function whether the user activates it or not; and (4) automatic setting and display management provision—TV users do not need to memorize and learn how to go back to the initial display management setting. When the user turns off the TV set, it will automatically return to the initial setting when it is turned on again.

TV games are popular entertainment for children. Good design features indicated by the interviewees include: (1) comprehensible icons—users can easily identify menu option icons in games; (2) unambiguous function grouping—games always use a meaningful group function rule so users can easily locate the function; (3) legible text display—TV games fit information presentation into the display space so children can read the
An Activity-Oriented Approach to Designing a User Interface for Digital Television

instruction; (4) easy-to-use function keys—all function keys are unambiguously mapped to the player’s task; (5) context-sensitive help—when playing a TV game, the player does not need to refer to the manual. Help information for each possible problem is always provided to the player throughout the game play.

PC users pointed out several good design features of a PC: (1) interactivity—PC provides interactive functions and dynamic feedback allowing users to use appropriate commands to achieve their task goal; (2) graphical user interface—PC contains easy-to-understand icons and intuitive metaphor that makes users feel they are directly manipulating the device; (3) direct linkage to related information—the hyperlink mechanism helps users easily and efficiently locate information they are interested in; (4) multi-tasking—users can perform more than one task simultaneously. PC users wished that DTV would also allow users multiple viewing of TV programs and services at the same time.

These good design features provide insight into DTV design. They can also be used as design references to ensure interoperability of networked products.

Exploring Users’ Mental Models and Preferences

Respondents with low interaction skills, such as housewives and older adults, stated their preference for TV interaction style. In fact, even respondents with high interaction skill expected DTV to retain a TV context for entertainment activities, while good PC design features provide support for information-related activities. TV design features all respondents would like to retain on DTV were: (1) TV screen as a default screen, (2) remote control as the main interaction device, (3) shallow menu structure, (4) automatic display settings, and (5) direct access function keys.

The User Interface Design Concept

This study developed a user interface concept based on both activity and user requirements. The concept and the features are described next.

Activity-Oriented User Interface Flow

The use model obtained from ethnographic research served as the design basis for the user interface structure. In this design, services are provided in accordance with activity needs. In addition, services are embedded in the activity so that users need only focus on the activity without contemplating how to apply appropriate services to support the activity. For example, when the user chooses the activity he/she wants to engage in, he/she may get related services in the service menu. Also, when the user uses a service to perform an activity, the system will automatically display related functions. In so doing, users’ cognitive load can be reduced.

Remote Control for Universal Access

Survey data showed that most respondents preferred to use a remote control as the primary interaction device. The remote control design is intended to support users with different interaction skills. Thus, in our design, the remote control is divided into two areas: the primary control area and the advanced control area (Figure 1). The primary control area is similar to the traditional analog TV remote control. It provides basic function keys (e.g., number key, volume up/down, channel up/down, mute, and so on) sufficient for operating multimedia devices. The primary control area also provides eight function keys dedicated to frequently performed activities identified from the activity analysis. The function keys allow users direct access to critical services or programs for those activities. The primary control area is designed mainly for supporting entertainment and
An Activity-Oriented Approach to Designing a User Interface for Digital Television

daily life activities. The advanced control area is a touch pad serving several functions: (1) points and selects menu items, (2) inputs text, (3) displays personalized Electronic Program Guide, and (4) manages displays. It is suitable for information, transaction, and education activities.

**Shallow Menu Hierarchy**

To provide a simple use environment, the menu function items were arranged based on importance and frequency-of-use for each service. The sequential menus were limited to three layers, helping users avoid unnecessary menu traversal. For simpler operation, menu items can be selected using arrow keys to move the cursor and then pressing the enter (ok) key. Moreover, eight hot keys on the remote control provide direct access to critical activity group services (Figure 2) so that menu traversal is minimized.

**Multiple Viewing and Display Management**

To accommodate single and multiple viewing behaviors, two display modes (single viewport and multiple viewport) are provided. The single-view mode is designated as a default mode. When the DTV is turned on, it displays single-view mode (Figure 3a). In the single-view mode, if another service or program is selected, the DTV will automatically switch to multiple-view mode (Figure 3b). In the design, the system supports up to four active viewports at the same time. With multiple-view mode display, the user can resize and relocate the viewports at will, or go back to the initial single-view mode by pressing the cancel key on the remote control.

**Adaptive Information Presentation**

In the multiple-view mode, display information legibility may suffer. To solve this problem, our study developed an adaptive information presentation method. The method contains two mechanisms: menu legibility adjustment and content legibility. Menu legibility affects how many menu options can be displayed. The adaptive information presentation method automatically adjusts the numbers of legible options for viewport size to ensure menu option legibility. Content legibility affects how much information can be displayed. The adaptive information presentation...
method decides which information is displayed according to its importance. When a display space is reduced, only important information will be displayed, and font size is automatically adjusted to keep information legible (Figure 3b and 4). In addition to the adaptive information presentation method, the system also provides a virtual magnifying glass that enlarges focused content while it shrinks the neighborhood area using a fisheye display method.

**Context-Sensitive Menu Functions**

To avoid unnecessary menu traversals, functions appropriate to the current use context are provided to users. The context-sensitive menu functions can detect a user’s location in the activity menu context and provide suitable activity support options. The functions are displayed in a menu bar and numbered in terms of their appropriateness (Figure 4).

**USABILITY EVALUATION**

The purpose of usability evaluation is twofold: (1) assessing user interface design usability, and (2) evaluating usefulness of each user interface design feature from the user’s point of view.

**Participants**

Twenty subjects participated in the usability evaluation. In order to represent user population,
the recruited participants included 11 high skill level subjects (i.e., three high school students, four college students, four middle-aged technical professionals) and nine low skill level subjects (i.e., three children in elementary school, three middle-aged housewives, and three older adults). They all regarded themselves as early adopters of DTV when they answered the survey question.

**Material, User Tasks and Procedures**

A user interface concept prototype was developed using Microsoft Visual C++. The prototype simulated the user interface to support three kinds of activities: entertainment, transaction, and information browsing. A liquid-crystal display (LCD) TV was used to display the prototype. The experimental environment is shown in Figure 5.

Before the usability evaluation session began, the experimenter introduced the evaluation procedure and tasks to the participants. In the evaluation stage, subjects were asked to perform tasks by following a test scenario. The test scenario represented activities frequently engaged in by family members in a morning. It consisted of three scenarios: (1) searching for news/movie program, (2) browsing information, and (3) shopping on TV. Each activity scenario in turn contained several tasks (Table 2). Specifically, the searching for news/movie program scenario involved three tasks: (1) selecting a TV program from the program guide, (2) browsing a movie from a video-on-demand (VoD) service, and (3) scheduling a program recording. The information-browsing scenario illustrated daily information-related activities such as checking weather, stock information, and traffic information. Finally, the TV shopping task simulated TV-shopping behavior including searching for products, browsing product information, comparing different products, and engaging in online transactions.

When performing these tasks, subjects were asked to think aloud through every task step. After performing the tasks, performance data (task error rate and verbal protocol) were recorded. Upon each task completion, subjects rated the perceived usefulness (five-point Likert scale: 1-non-useful, 5-very useful) and perceived usability (five-point Likert scale: 1-unusable, 5-easy to use) of each user interface feature.

**RESULTS**

**Task Performance**

**Scenario 1: Searching for News/Movie Programs**

In the searching for news/movie programs scenario, almost all operations were error free, except that a few subjects made an error at the

---

Figure 5. The experimental environment
An Activity-Oriented Approach to Designing a User Interface for Digital Television

step “press function key (error rate = 0.4)” in the scheduling a program recording task (Table 3). In order to understand why subjects made such an error, we had a debriefing interview with subjects who made the error. We found that the low skill group subjects expected to find the “record” key on the remote control, while the high skill group subjects anticipated that the “record” function was in the main menu on the screen. These expectations were not consistent with our design. In our design, the “record” function is only embedded in the context sensitive function bar. The result caused us to reconsider adding an array of the hard function keys on the remote control for those frequently used functions (e.g., record, play, stop, forward, back).

Scenario 2: Browsing Information

There is only one operational error found in this scenario (Table 4). Subjects made errors in the “select the information item” step of the information-browsing task (error rate = 0.15). After completing the task, we interviewed the subjects and found that three low-skilled subjects did not understand what “submenu” means, because they

</tbody>
</table>
did not have any computer experience. In revising the menu design, we considered providing a clue to guide the low-skill user group when they interact with the TV menu. Or, we would also provide a number key input for the low skill group to allow them direct function access.

Scenario 3: Shopping on TV

All subjects not only understood how to perform the TV shopping task but were also able to complete it within a short time. In the debriefing interview, we asked subjects why they were so skilled. Subjects indicated that they felt the TV shopping functions were similar to real life shopping situations. In addition, the function arrangement in the menu structure was easy to understand and navigate.

Evaluation of Usefulness for Each User Interface Design Feature Activity-Oriented User Interface Flow

All subjects were able to follow the user interface structure to perform TV viewing, information retrieving, and transaction activities with minimal errors (mean error rate = 0.03%). Subjects felt that the activity-oriented user interface flow was useful (mean of perceived usefulness = 4.50, Std. = 0.83) and usable (perceived ease of use = 4.30, Std. = 0.98) for the TV-shopping task. With this design feature, they did not have to search for the service they needed at every task step. That is, the system automatically provided relative information and functions to support the TV-shopping task without traversing through multiple service menus. Therefore, they were not afraid that they might get lost while performing the task.

Shallow Menu Structure

Twenty users gave a high rating of perceived usefulness (mean = 3.60, Std. = 1.23) and perceived usability (mean = 3.80, Std. = 1.11) to this design feature when they completed three information retrieving, VoD, and TV-shopping activities. Subjects were able to complete tasks without making any errors (mean error rate = 0.00). Time recordings of menu navigation indicated that the subjects did not need much time thinking about where to go next. Furthermore, the verbal protocol did not show that subjects experienced any frustration or confusion.

Multiple Viewing and Viewport Management

The multiple-viewing feature was evaluated by the information browsing activity. Technical professionals and students exhibited higher acceptance (i.e., mean of perceived usefulness = 4.07 Std. = 0.37; mean of perceived ease of use = 4.36, Std. = 0.74) of the multiple-viewing mode, while housewives (mean of perceived usefulness = 2.33, Std. = 0.58) and older adults (mean of perceived usefulness = 1.67, Std. = 0.58) had problems with this feature. The former expressed that the multiple-view mode was convenient for them because they could use the information service while they were watching a TV program. However, the latter just wanted to use single-view mode. If multiple-view mode were the only choice, housewives and older adults hoped that the system manufacturer could provide an automatic display management function. Although this design feature may not be well received by housewives and older adults, their task performance was still above the baseline (mean of perceived ease of use = 3.50, Std. = 0.58).

Adaptive Information Presentation

This feature was well received by all subjects (mean of perceived usefulness = 3.85, Std. = 1.27) in information-browsing tasks, especially for older adults. It can enhance displayed information legibility. However, a concern was raised that adaptive information presentation might cause a side effect, that is, increasing font size may decrease the number of menu options displayed and consequently hamper menu interaction performance. However, usability evaluation results indicated that this was not the case. Results revealed that it did not have a negative effect on menu selection or searching for menu options (mean of perceived ease of use = 3.85 Std. = 1.27). In fact, it enhanced menu interaction performance for older adults.

Context-Sensitive Functions

All subjects gave high marks to this design feature. Students and housewives expressed that this design feature was helpful (mean of perceived usefulness = 3.80, Std. = 1.01) and usable (mean of perceived easy to use = 4.00, Std. = 1.08) be-

CONCLUSION

This study attempts to apply an activity-oriented design approach to digital TV. This approach analyzes activities and identifies requirements for each type of activity. Activity-oriented user interface flow can help users complete their activities and reduce their workload. The evaluation results support this notion, and services are considered to be accessible to users and useful in supporting activities.

This study also explores good design features of related products used by users for the same activities. Incorporating good design features of related products into the new design not only eases the learning process for the new product, but also helps establish a familiar and comfortable feeling for first-time users. This helps users gain out-of-the-box experience (Ketola, 2005).

We also found that different user groups have different user interface expectations. For example, technicians and students prefer multiple viewing and multiple tasks. On the contrary, older adults prefer a simple TV environment. Therefore, the proposed design concept is flexible enough to accommodate these two types of interaction methods in order to meet two separate user requirements.

ABSTRACT

The introduction of computing and communications technologies within cars raises a range of novel human-computer interaction (HCI) issues. In particular, it is critical to understand how user-interfaces within cars can best be designed to account for the severe physical, perceptual and cognitive constraints placed on users by the driving context. This chapter introduces the driving situation and explains the range of computing systems being introduced within cars and their associated user-interfaces. The overall human-focused factors that designers must consider for this technology are raised. Furthermore, the range of methods (e.g., use of simulators, instrumented vehicles) available to designers of in-car user-interfaces are compared and contrasted. Specific guidance for one key system, vehicle navigation, is provided in a case study discussion. To conclude, overall trends in the development of in-car user-interfaces are discussed and the research challenges are raised.

INTRODUCTION

The motor car is an integral part of modern society. These self-propelled driver-guided vehicles transport millions of people every day for a multitude of different purposes, for example as part of work, for visiting friends and family, or for leisure activities. Likewise, computers are essential to many peoples’ regular lives. It is only relatively recently that these two products have begun to merge, as computing-related technology is increasingly implemented within road-going vehicles. The functions of an in-car computing system can be broad, supporting tasks as diverse as navigation, lane keeping, collision avoidance, and parking. Ultimately, by implementing such systems car manufacturers aim to improve the safety, efficiency, and comfort and entertainment of the driving experience (Bishop, 2005).

Designing the user-interface for in-car computing systems raises many novel challenges, quite unlike those traditionally associated with interface design. For instance, in many situations, the use of an in-car system is secondary to the complex and already demanding primary task of safely
controlling a vehicle in 2D space, whilst simultaneously maintaining an awareness of hazards, largely using the visual sense. Consequently, the level of workload (physical, visual, and mental) when using displays and controls becomes a critical safety-related factor. As a further example, in-car computing systems have to be used by a driver (and possible also, a passenger) who is sat in a constrained posture and is unlikely to be able to undertake a two handed operation. Therefore, the design (location, type, size, etc.) of input devices has to be carefully considered, accounting in particular for comfort, as well as safety, requirements.

This chapter aims primarily to provide the reader with an overall awareness of novel in-car computing systems and the key HCI design and evaluation issues. The focus is on the user-interface, that is, “the means by which the system reveals itself to the users and behaves in relation to the users’ needs“ (Hackos & Redish, 1998, p.5). Topics of relevance to both researchers and practitioners are raised throughout. Given the complexity of the driving task and the wide range of computing systems of relevance, the chapter principally provides breadth in its consideration of the subject. Nevertheless, some depth is explored in a case study investigation on the design and evaluation of user-interfaces for vehicle navigation systems.

**TYPES OF IN-CAR COMPUTING SYSTEMS**

Technology is increasingly being seen to have a critical role to play in alleviating the negative aspects of road transport, such as congestion, pollution and road traffic accidents (Bishop, 2005). Many technological initiatives are considered under the umbrella term, intelligent transport systems (ITS), where “ITS provides the intelligent link between travelers, vehicles, and infrastructure“ (www.itsa.org, September, 2006). In this respect, in-vehicle computing systems are an important facet of ITS. Specifically, there are two core types of computing and communications systems which are either being implemented or developed for use in vehicles:

- **Information-based systems:** These systems provide information relevant to components of the driving environment, the vehicle or the driver. Examples of systems include navigation (facilitating route planning and following), travel and traffic information (traffic conditions, car parking availability, etc.), vision enhancement (providing an enhanced view of the road ahead, when driving at night, in fog or in heavy rain), driver alertness monitoring (informing the incapacitated driver if they are unfit to drive) and collision warnings (presenting warnings or advice regarding hazards).

- **Control-based systems:** These systems affect the routine, operational elements of the driving task. Examples of systems include adaptive cruise control (where the car is kept at a set time gap from a lead vehicle), speed limiting (the car speed cannot exceed the current limit), lane keeping (the driver’s vehicle is kept within a given lane), self parking (vehicle automatically steers in low speed operation to position itself within a selected parking space) and collision avoidance (the vehicle automatically responds to an emergency situation). Clearly, such systems fundamentally change the nature of what we consider to be ‘driving.’

It is important to note that there is a third category of in-car computing system, those which do not provide any functionality to support the driving task. These systems are an important consideration though, as they can negatively influence safety, particularly through the potential for distraction (Young, Regan & Hammer, 2003). Such systems may aim to enhance work-oriented productivity.
whilst driving (e.g., mobile phones, e-mail and Internet access) or be primarily conceived for entertainment and comfort purposes (e.g., music and DVD players, games). Moreover, they may be designed for dedicated use in a vehicle or for operation in a range of different contexts (often termed nomadic devices).

OVERALL HUMAN FACTORS ISSUES

Driving is a complex task involving a large number of subtasks that can be conceptualised as existing within three levels of an overall hierarchical structure (Michon, 1985):

- Strategic tasks (highest level global travel decisions—e.g., which car to take, which route to take);
- Tactical tasks (making concrete manoeuvres requiring interaction with other road users—e.g., changing lane, turning at a roundabout);
- Operational tasks (motor execution of tasks planned at higher levels—e.g., turning steering wheel, pressing brake).

Inevitably, the introduction of new technologies into the driving context will have a considerable impact across all three levels. As a result, there are many human-focused issues that must be considered in the design and evaluation process for in-car computing systems. To provide structure to a discussion of these issues, two overall scenarios are envisaged which may arise from poor design and/or implementation of the technology.

- **Overload:** Many of these systems (particularly those providing novel types of information and/or interactions) lead to situations in which a driver must divide their attention between core driving tasks (e.g., watching out for hazards) and secondary system tasks (e.g., inputting information). Furthermore, systems may provide excessive information in an inappropriate way leading to high levels of mental workload, stress and frustration. Such issues often manifest themselves as distraction to the driver (biomechanical, visual, auditory and/or cognitive).

- **Underload:** Control-based systems clearly automate certain aspects of driving, transferring certain responsibilities from operator to computer (e.g., staying in lane), whilst potentially providing new tasks for the driver (e.g., monitoring system performance). Automation is a fundamental human factors topic with a considerable research literature (see Wickens et al., 2004). Key concerns in this context relate to the potential for a driver exhibiting reduced situational awareness (e.g., for other road users), negative behavioral adaptation (e.g., by taking greater risks) and de-skilling (e.g., driver not able to resume control in the event of system failure).

THE HUMAN-CENTRED DESIGN PROCESS

The fundamental components of a human-focused approach hold true for in-car computing, as much as for any interactive product or system, that is, early focus on users and tasks, empirical measurement and iterative design (Gould & Lewis, 1985). A comprehensive understanding of the context in which in-car computing devices will be used is especially important early in the design process. Context of use refers to “the users, tasks and equipment (hardware, software, and materials), and the physical and social environments in which a product is used” (Maguire, 2001, p.457).

A context of use analysis assists in developing the initial requirements for a design and also provides an early basis for testing scenarios. Moreover, context of use analysis provides a focused ap-
Designing and Evaluating In-Car User-Interfaces

proach that helps to ensure a shared view among a design team. In the driving situation, there are several context of use issues which will have a significant effect on how an in-car computing system is subsequently designed. Accounting for these raises many unique challenges for in-car user-interface designers.

Users

As with many other consumer products, there will be a large variability in user characteristics (e.g., in perceptual and cognitive abilities, computer experience, anthropometry) to consider when designing in-car computing systems. Car manufacturers may have particular socio-economic groups in mind when designing a vehicle, but the user base may still be extremely large.

One fundamental individual difference factor often addressed in research is driver age—drivers can be as young as 16 (in certain countries) and as old as 90. In this respect, younger drivers may be particularly skilled in the use of computing technology, in comparison with the population at large, but are especially prone to risk taking (Green, 2003). Moreover, studies have shown a limited ability to divide attention and prioritize sources of information, largely due to lack of driving experience (Wickman, Nieminem & Summala, 1998). Subsequently, system block outs, which prevent the use of complex functions in inappropriate driving situations, are likely to be of particular benefit for these individuals.

In contrast, older drivers often suffer from a range of visual impairments that can lead to a range of problems with in-vehicle displays. For instance, presbyopia (loss of elasticity in the lens of the eye) is extremely common amongst older people, as is reduced contrast sensitivity. Studies consistently show that older drivers can take 1.5 to 2 times longer to read information from an in-vehicle display compared to younger drivers (Green, 2003). Given that drivers have a limited ability to change the distance between themselves and an in-vehicle display, the size, luminance and contrast of presented information are obviously critical design factors.

Tasks

A key task-related issue is that the use of an in-car computing system is likely to be discretionary. Drivers do not necessarily have to use the system to achieve their goals and alternatives will be available (e.g., a paper map, using the brake themselves). As a result, the perceived utility of the device is critical. Furthermore, drivers’ affective requirements may be particularly important. In certain cases, this requirement may conflict with safety-related needs, for instance, for a simple, rather than flashy or overly engaging user-interface.

The factor that most differentiates the driving context from traditional user-interface design is the multiple-task nature of system use, and in this respect, there are two critical issues that designers must take into consideration. The first concerns the relationship between primary driving tasks and secondary system tasks, as drivers seek to divide their attention between competing sources of information. Driving is largely a performance and time-critical visual-manual task with significant spatial components (e.g., estimating distances). Consequently, secondary tasks must not be overly time-consuming to achieve or require attentional resources that are largely visual, manual, and spatial in nature, if they are to avoid having a significant impact on primary driving.

A second fundamental issue is the amount of information processing or decision making required for successful task performance, known as mental workload (Wickens et al., 2004). Novel in-car computing systems may provide functionality of utility to a driver or passengers, but interaction with the technology will inevitably increase (or in some cases decrease) overall workload. Context is very important here, as driving is a task in which workload varies considerably
Designing and Evaluating In-Car User-Interfaces

from one situation to another (compare driving in city traffic versus on the motorway). In this respect, certain authors (e.g., Green, 2004; Jones, 2002; Markkula, Kutila, & Engström, 2005) have taken the view that workload managers must be developed which make real-time predictions of the workload a driver is under and only present information or enable interactions to occur when overall workload is considered to be at an acceptable level. As an example, an incoming phone call may be sent straight to voice mail when the driver is considered to be particularly loaded (e.g., when driving in an unfamiliar city), but may be permitted in a lower workload scenario (e.g., driving along a dual carriageway and following a lead vehicle). Simple workload managers already exist in some vehicles (e.g., http://driving.timesonline.co.uk/article/0,,12929-2319048,00.html, September 2006), nevertheless, there are several complex research issues which must be addressed to fully realize the benefits of adaptive software in this context. For instance, workload managers need a comprehensive and accurate model of the driver, driving tasks and the driving environment. Given the vast range of variables of relevance to these categories, many of which do not lend to accurate and reliable measurement, extensive workload managers are likely to remain in the research domain for several years.

Equipment

The driving situation necessitates the use of input and output devices which are familiar to the majority of user-interface designers (pushbuttons, rockers, rotaries, LCDs, touchscreens, digitized or synthesized speech), together with equipment which is perhaps less known. For instance, there is a considerable research literature regarding the use of Head-Up Displays (HUDs) within vehicles. A HUD uses projection technology to provide virtual images which can be seen in the driver’s line of sight through the front windscreen (see Figure 1). They are widely used within the aviation and military fields, and are now beginning to be implemented on a large-scale within road-based vehicles. HUDs will potentially allow drivers to continue attending to the road ahead whilst taking secondary information more quickly (Ward & Parkes, 1994). As a consequence, they may be most applicable to situations in which the visual modality is highly loaded (e.g., urban driving), and for older drivers who experience difficulties in rapidly changing accommodation between near and far objects (Burns, 1999).

From a human-focused perspective, there are clear dangers in simply translating a technology from one context to another, given that vehicle-based HUDs will be used by people of varying perceptual and cognitive capabilities within an
Designing and Evaluating In-Car User-Interfaces

environment where there is a complex, continually changing visual scene. Specifically, researchers have established that poorly designed HUDs can mask critical road information, disrupt distance perception and visual scanning patterns, and negatively affect the ability of drivers to detect hazards in their peripheral vision (known as perceptual tunneling)—summarized by Tufano (1997) and Ward and Parkes (1994). Critical design factors that emerge from these findings include: display complexity; contrast and luminance; color choice; size of image; spatial location; and virtual image distance. Perhaps the most important design-related requirements are to consider carefully what and how much information is most appropriate to present on a HUD. There are temptations for designers to present ever-increasing amounts of information on HUDs. However, in contrast with traditional in-vehicle displays, a HUD image, by its very presence in the driver’s line of sight, will demand focused attention (Burnett, 2003).

Environments

The physical environment is also a specific area that designers need to be aware of. In particular, the light, sound, thermal and vibration environment within a car can be highly variable. A range of design requirements will emerge from a consideration of these factors, for instance, potential for glare, problems with speech interfaces, use with gloves, and so on.

From anthropometric and biomechanical perspectives, the vehicle cabin environment provides many challenges for designers. This is an area in which designers make considerable use of CAD modeling to analyze different locations for displays and controls, ultimately aiming to ensure good fit for the design population. However, drivers sit in a constrained posture, often for several hours and have limited physical mobility (e.g., to comfortably view displays or reach controls). Consequently, there is limited space within a vehicle for the placement of a physical user-interface, a key problem for designers hoping to implement additional functionality within the vehicle.

To a large extent, this factor has fueled the development of multi-modal user-interfaces, where a small number of controls, together with menu-driven screens, provide access to many functions within the vehicle. Clearly, such visually-oriented user-interfaces are likely to promote a considerable amount of “eyes-off-road” time, and empirical studies have confirmed this prediction (Dewar, 2002). Moreover, users mistaking the current mode is a well-established problem in user-interface design, and clear feedback is an important design requirement (Preece, Rogers & Sharp, 2002). In many respects, there is a trade-off in design between the number of discrete controls that a user must scan within a vehicle and the number of levels within a menu-based system that must be explored and understood. This is a very similar problem to that considered by HCI researchers in the 1980s and 1990s interested in the breadth versus depth of menus in graphical user-interfaces (Shneiderman, 1998). An overall recommendation from such HCI research is that breadth should generally be favored over depth, as excessive depth can cause considerably more problems for the user than an equivalent breadth, largely due to the cognitive problems of navigation (Shneiderman, 1998). Whilst such guidance is considered to be of relevance to the design of in-car computing, research is still required which considers the trade-off existing in the multiple-task driving environment.

METHODS FOR USE IN DESIGN AND EVALUATION

In considering the range of methods that a designer can utilize when designing and evaluating in-car computing systems, the first difficulty is in establishing what is meant by a method. In this respect, a “human factors method for testing
Designing and Evaluating In-Car User-Interfaces

in-car systems” can be seen to be a combination of three factors:

1. Which environment is the method used in (road, test track, simulator, laboratory, etc.). As can be seen in Figure 2 (redrawn and adapted from Parkes, 1991), there is a fundamental trade off in choosing a method environment between the need for control and the validity of results. Choosing an environment will also be largely influenced by practical considerations, the knowledge/skills of the design and evaluation team and resource limitations.

2. Which task manipulations occur (multiple task, single task loading, no tasks given, etc.)? In certain methods, there is an attempt to replicate or simulate the multiple task nature of driving. For other methods, performance and/or behavior on a single task may be assessed and the potential impact on other tasks inferred from this. Most removed from actual driving, some methods do not involve users, but instead aim to predict impacts or issues, for instance through the use of expert ratings or modeling techniques.

3. Which dependent variables (operationalized as metrics) are of interest. In assessing an in-car computing user-interface, a large range of possible metrics could be implemented. Some will relate to drivers’ performance with primary driving tasks (e.g., lane position, hazard detection) or their use of primary vehicle controls (e.g., use of brake, steering wheel). Other metrics focus on driver performance and/or the demand of secondary tasks (e.g., task times, errors, display glances). As noted by Parkes (1991), usability evaluations of in-car computing devices should incorporate a wide range of measures relevant to the different levels of the driving task. For instance, at the strategic level, observation techniques and surveys are of relevance, whereas verbal protocols, interviews and questionnaires can capture the behavior of drivers at the tactical level. As noted by Parkes, such an approach provides “complete, rather than partial, pictures of product usability” (p.1445).

There is presently considerable research investigating specific methods for use in the design and evaluation of in-car user-interfaces. As noted by Preece et al. (2002), in deciding on any HCI method, the design team must consider the overall goals of the work, specific questions to be addressed, the practical and ethical issues and how data will need to be analyzed and reported. For

Figure 2. Environments for evaluation of in-car computing devices and the relationship between validity and control
in-car computing, these principles still hold, and many of the same global techniques used in the HCI area (for example, questionnaires, interviews, guidelines/checklists) will be used. However, by necessity, bespoke methods (or at least specific versions of generic methods) are required that account for the particular complex, safety-critical characteristics of the driving context. The following section summarizes key methods currently used and highlights some of the important research issues under investigation. Moreover, primary advantages and disadvantages are given. Table 1 summarizes some of the key issues.

### Field Trials

Participants are given a car fitted with an operational system for several months for use in everyday activities. This method tends to look at broad issues relating to the long-term use of a system, for example, drivers’ acceptance of the technology, and whether any behavioral adaptation effects arise. Objective data can be measured using on-board instrumentation (e.g., cameras, speed sensors) whereas subjective data is often captured using survey or interview-based approaches. Clearly, such a method provides an ecologically valid test of a system, and is particularly

</tbody>
</table>
appropriate to the late stages of the design process where a robust prototype is available. Nevertheless, field trials can be extremely expensive and various ethical and liability considerations must be accounted for. An example of a field trial that was carried out in Sweden concerned drivers’ use of intelligent speed adaptation systems (whereby a vehicle’s speed is automatically kept within the speed limit for the current area. Wallen, Warner & Aberg, 2005).

Road Trials

Drivers take part in a short-term (normally less than one day) focused study using a system in an instrumented car on public roads (occasionally on test tracks). For such trials, a wide range of variables may be measured and analyzed (e.g., visual behavior, workload, vehicle control, subjective preference) depending on the aims of the study. Road trials enable more experimental control than field trials, but are still potentially affected by a wide range of confounding variables (e.g., traffic conditions, weather). Furthermore, such a method remains costly to implement and requires robust protocols to ensure the safety of all concerned. Many road trials are reported in the literature, particularly concerning information and entertainment/productivity oriented systems. For instance, Burnett and Joyner (1997) describe a study which evaluated two different user-interfaces for vehicle navigation systems.

Simulator Trials

Drivers take part in a short-term (normally less than one day) focused study using a system fitted or mocked up within a driving simulator. The faithfulness that a simulator represents the driving task (known as its fidelity) can vary considerably, and configurations range from those with single computer screens and game controller configurations, through to real car cabins with multiple projections and motion systems. An example of a medium fidelity driving simulator is shown in Figure 3.

Driving simulators have become increasingly popular in recent years as a result of reduced hardware and software costs, and potentially offer an extremely cost-effective way of investigating many different design and evaluation issues in a safe and controlled environment (Reed & Green, 1999). Nevertheless, there are two key research issues concerning the use of driving simulators. Firstly, it is well known that individuals can experience symptoms of sickness in driving simulators, manifested as feelings of nausea, dizziness, and headaches. There has been considerable research regarding such sickness in virtual environments, and whilst there is still debate regarding the

Figure 3. Example of a medium fidelity driving simulator
Designing and Evaluating In-Car User-Interfaces

theoretical basis for the phenomenon (see for instance Nichols & Patel, 2002), there is practical guidance for those using driving simulators. For instance, screening questionnaires can be used to eliminate individuals who are most likely to experience sickness during a trial (Kennedy et al., 2001). Furthermore, various countermeasures can be used in the development of the simulator and its environment to reduce the prevalence of sickness (e.g., high, consistent frame rate, air-conditioning, natural background lighting. Nichols & Patel, 2002).

A second and more complex issue concerns validity, particularly behavioral (or construct) validity, that is, the extent to which drivers behave in the simulator as they would in the real world (Blaauw, 1982; Reed & Green, 1999). Driving simulator validity is problematic to study for several reasons. Running both road and simulator trials which are comparable (in terms of participants, tasks, measures, procedures, etc.) can be extremely difficult to achieve, and ultimately will be resource intensive. Furthermore, validity in this area is widely recognized to be a function of a large number of variables, including those relating to how the vehicle is represented (e.g., primary and secondary control design, the sense of enclosure, viewing angles, engine noise, vibration, motion, etc.) and those concerning the driving environment (e.g., visual field of view, screen resolution, graphical complexity, traffic representation, wind/road noise, etc.) Kaptein et al., 1996; Peters & Peters, 2002). Most importantly, our understanding of validity must consider the driving task itself. Driving is a complex task, involving a substantial number of discrete physical, perceptual and cognitive behaviors, and a specific simulator configuration will only enable a subset of these to be investigated (e.g., speed control, headway maintenance).

As a consequence, despite the importance of the topic, there are few driving simulator validity studies in the open literature. Moreover, various limitations can be expressed for previous research in this area:

• It is difficult to generalize from existing validity studies, as they tend to be very specific to (a) the simulator configuration under investigation, and (b) the technology (hardware and software) available at that time (see for instance, Tornros (1998) compared with Blaauw (1982)).
• Studies inevitably only concern a small number of variables, for instance the effect of screen resolution and forward field of view on speed and headway choice (Jamson, 2001); or the effect of characteristics of torque feedback for steering on curve negotiation (Toffin et al., 2003).
• Studies often do not report critical data regarding the simulator configuration (e.g., steering sensitivity, max/min acceleration, driver eye height) which, for given types of study will be critical in results interpretation and cross-study comparison.

Occlusion

This is a laboratory-based method which focuses on the visual demand of in-vehicle systems. Participants carry out tasks with an in-vehicle system (stationary within a vehicle or vehicle mock up) whilst wearing computer-controlled goggles with LCDs as lenses which can open and shut in a precise manner (see Figure 4). Consequently, by stipulating a cycle of vision for a short period of time (e.g., 1.5 seconds), followed by an occlusion interval (e.g., 1.5 seconds), glancing behaviour is mimicked in a controlled fashion. Occlusion offers a relatively simple method of predicting visual demand, but is has been pointed out that its emphasis on user trials and performance data means that it requires a robust prototype and is therefore of limited use early in the design process (Pettitt et al., 2006).
Following considerable research, the occlusion method has recently been formalized as an international standard (ISO, 2005). In particular, guidance is given on how many participants are required, how much training to give, how many task variations to set, data analysis procedures, and so on. Moreover, two key metrics are stipulated: total shutter open time (the total time required to carry out tasks when vision is available); and resumability (the ratio of total shutter open time to task time when full vision is provided). For resumability, there is considerable debate regarding the merit of the measure. Advocates believe the metric provides an indication of the ease by which a task can be resumed following a period without vision (Baumann et al., 2004). Critics point out that the metric is also influenced by the degree to which participants are able to achieve tasks during occluded (non-vision) periods (Petitt et al., 2006). Consequently, it can be difficult for a design team to interpret the results of an occlusion trial.

**Peripheral Detection Task**

This method requires drivers to carry out tasks with an in-car system (either on road or in a simulator) and to respond to the presence of lights within their periphery. The speed and accuracy of responses are considered to relate to the mental workload and distraction associated with secondary tasks (Young et al., 2003). The advantage of this method over occlusion is that it offers an assessment of cognitive, as well as visual demand (of relevance to the assessment of speech interfaces, for instance). The primary disadvantage is that the method still requires some form of driving task. Moreover, in contrast with occlusion, the method has not been fully standardized, and the ability to make cross study comparisons is severely limited by the specific choice of driving task scenarios (affecting task load and the conspicuity of the peripheral stimuli). It has also been noted that it is very difficult to discern between the level of cognitive demand and the visual demand for a given user-interface (Young et al., 2003).

An interesting recent development addresses some of these limitations. Engstrom, Aberg and Johansson (2005) considered the potential for the use of a haptic peripheral detection task, where drivers respond to vibro-tactile stimulation through the wrist whilst interacting with an in-vehicle system. Clearly, such a variation of peripheral detection is not affected by variations in lighting conditions. Furthermore, the authors argue on the basis of their validation work that this method provides “a ‘pure’ measure of cognitive load not mixed up with the effect of simply looking away” (p.233).
Lane Change Task

This method occurs in a basic PC simulated environment in which drivers are requested to make various lane change maneuvers whilst engaging with an in-vehicle system. The extent to which the profile of maneuver made by a driver varies from the optimum maneuver (the normative model) is considered to be a measure of the quality of their driving. Specifically, the method has the ability to assess the impact of an in-car computing system on a driver’s awareness of the driving environment (perception, reaction), and, their ability to safely control the vehicle (maneuvering, lane keeping) Mattes (2003). Considerable research is ongoing with the lane change task in an attempt to develop an international standard (Transport Canada, 2006). Key research issues concern participant choice, training requirements and developing acceptable limits for performance.

15 Second Rule

Participants carry out tasks with an in-car computing system whilst stationary within a vehicle or mock up (i.e., with no driving task) and with full vision. The mean time to undertake a task is considered to be a basic measure of how demanding visually it is likely to be when driving (Green, 1999). A “cut-off” of 15 seconds has been set by the Society for Automotive Engineers (SAE). If the task on average takes longer than 15 seconds to achieve when stationary, it should not be allowed in a moving vehicle. The method is simple to implement and has the key advantage that it has been formalized in an SAE statement of best practice (SAE, 2000).

Research by Green (1999) and other research teams (e.g., Pettitt et al., 2006) has shown strong correlations between static task times and the total amount of time spent looking away from the road at displays/controls, both in simulator and road studies. However, the correlation between static task times and the duration of single glances towards an in-vehicle display is generally poor. This is important because a user-interface may promote a small number of very long glances (e.g., as a result of dynamically changing visual information) which can have a considerable negative effect on driving performance (Burnett & Joyner, 1997). It is for this primary reason that many authors advocate the use of the occlusion method as a better low-cost method for investigating the visual demand of an in-car user-interface (Pettitt et al., 2006; Stevens et al., 2004).

Keystroke Level Model (KLM)

The KLM method from the GOMs family of techniques is well known to HCI researchers and (to a lesser extent) practitioners (Preece et al., 2002; Shneiderman, 1998). It is a form of task analysis in which system tasks with a given user-interface are broken down into their underlying physical and mental operators, e.g., pressing buttons, moving hand between controls, scanning for information. This is a method that is extremely cheap to implement, as there is no need for participants, and the method can be used with very basic prototypes early in the design process. Time values are associated with each operator and summed to give a prediction of task times. Researchers have developed new operator values relevant to the in-car situation (e.g., time to search a visual display, locate a control, move hand back to steering wheel) and have reported strong correlations between predicted task times and times based on user trials (Green, 2003; Pettitt et al., 2005). Task times can be related to certain measures of visual demand for in-car user-interfaces.

In an extension of the KLM method, Pettitt, Burnett and Stevens (2007) recently developed new rules that enable designers to develop predictions for a broader range of visual demand measures. In particular, the extended KLM considers a time-line view of an interaction in which a cycle of vision/non-vision occurs with a user-interface (similar to the occlusion protocol).
The authors have found that their version of KLM can differentiate between tasks as effectively as does the occlusion technique, but recommend that further development is carried out to ensure that practitioners can utilize the method reliably.

CASE STUDY: VEHICLE NAVIGATION SYSTEMS

To ground many of the issues previously mentioned, a specific system type has been chosen for further discussion (vehicle navigation systems). Many of the individual points made for this system can be generalized and are applicable to other in-car computing technologies.

Vehicle navigation systems aim to support the strategic (e.g., route planning) and tactical (e.g., route following) components of the overall driving task. They have the greatest potential to assist drivers who undertake many unfamiliar journeys, for instance as part of work, or during leisure trips (e.g., when on holiday) and those who experience extreme difficulties with existing methods of navigation (particularly paper maps). When linked with reliable, real-time traffic information (thus providing dynamic guidance), the perceived utility of navigation systems to the everyday motorist is significantly enhanced (Bishop, 2005).

The market potential for vehicle navigation systems has already been demonstrated in Japan, where the technology has been available since the early 1990s. Approximately 40 percent of all vehicles on Japan’s roads now have a navigation system installed (http://www.jetro.go.jp/en/market/trend/topic/2004_12_carnavi.html, September 2006). In many other countries, the popularity of navigation systems is currently reduced in relation to Japan, but is predicted to rise rapidly over the next few years (Bishop, 2005).

The majority of human factors issues relevant to this form of technology relate to overload, although as shall be seen, underload is increasingly being researched. With respect to overload, clearly, a key concern is the potential for driver distraction and there has been considerable research on this topic since the mid 1980s (see Young et al., 2003 and Srinivisan, 1999, for reviews). In using a vehicle navigation system, drivers must interact with controls (e.g., to enter a destination, change map scale) and view/understand displays (e.g., to decide which turn to make, to examine options within a menu). In many cases, these interactions will arise when the vehicle is in motion. Consequently, to provide guidance for designers, researchers have aimed to understand how the user-interface design for a vehicle navigation system impacts on both navigating and primary driving performance. Specifically, research has aimed to answer the following three design-oriented questions:

What Information Should a Navigation System Provide?

To support route following, there are a wide range of different information types that a system could present, either referring to something real in the road environment (junction representations, street/road signs, landmarks, etc.) or indirectly referring to or pointing at aspects of the environment (distance to turn, directions, etc.). In this respect, researchers have established through a range of methodologies that the use of distinctive features of the environment (landmarks) within navigation instructions (e.g., “turn right at the church”) offer considerable advantages over the use of distance to turn information (e.g., “turn right in 300 meters” Burnett, 2000; Ross, May & Grimsley, 2004). Moreover, research has identified the fundamental characteristics of landmarks which designers of vehicle navigation systems and providers of underlying map databases must consider in choosing appropriate landmarks for presentation by a navigation system (Burnett, Smith & May, 2001).
How Should Information be Presented?

Navigation and related information has to be presented to the driver in some way, and there has been considerable research on a range of topics. One key concern has been the impact of system modality (voice and/or visual) on driving and navigating performance. The general consensus here is the primary modality for presentation of navigation instructions should be auditory to reduce the conflict with the predominately visual driving task. However, information should also be presented visually, in particular, to support driver’s understanding of more spatially complex maneuvers which cannot be represented easily in voice directions (Ross et al., 1995). Recently, Van Erp (2005) investigated empirically the potential for the use of passive touch as a novel modality for presentation of navigation instructions (specifically, vibro-tactile direction and distance to turn presented through the driver’s seat). They concluded that haptic navigation displays offer various advantages over visual displays, for example, they provide a ‘private’ display to the driver appropriate for very simple maneuvers. Nevertheless, it must be noted that the authors did not make comparisons with the prevailing visual and auditory interfaces. Other research related to information presentation has considered a wide range of issues, such as the format of information (map-based vs. turn-by-turn based), the scheduling of information (when to present instructions), and the location of information (positioning of displays). On these topics, the reader is directed to Ross et al. (1995) and Srinivisan (1999).

How Should Drivers Interact with a Navigation System?

For drivers (or passengers) to interact with a vehicle navigation system, there must be a means by which they can enter data (e.g., postcode for an address), select from continuous/discrete options (e.g., voice volume levels, stored destinations), request/repeat information (e.g., voice directions), and move through the system (e.g., within and between menu screens). There is understandably a natural tendency for designers to utilise the familiar desktop computing paradigms, thus utilizing specific hardware devices (e.g., joysticks, touchscreens, buttons) and associated software approaches (e.g., use of menus, lists, scrolling). Historically, such paradigms were conceived as a means of overcoming the significant limitations of command-line user-interfaces and provided a what-you-see-is-what-you-get (WYSIWYG) experience for the user (Shneiderman, 1998). In the driving context, several studies have shown that such highly visual-manual user-interfaces can have a considerable impact on safety (Nowakowski, Utsui & Green, 2000; Tijerina, Palmer & Goodman, 1998).

As an alternative to such user-interfaces, speech shows promise as a largely non-visual/manual input method for navigation systems (Tsimhoni, Smith, & Green, 2002). Nevertheless, research has also shown that there is considerable potential for cognitive distraction with speech interfaces (Gärtner, König, & Wittig, 2001), and it is critical that recognition accuracy is very high. Moreover, designers must provide clear dialogue structures, familiar vocabulary, strong feedback and error recovery strategies. These issues are of particular importance given the potentially large number of terms (e.g., towns, street names) that might be uttered and the difficulties that a speech recognition system can experience with alphabet spelling (specifically, the ‘e-set’—b, c, d, e, g etc.).

Recent research has also shown the potential for handwriting recognition in a driving context for inputting alphanumerical data (Burnett et al., 2005; Kamp et al., 2001). Whilst handwriting requires manual input, there is a reduced cognitive component and it is a more familiar method for users in contrast with speech interfaces. Nevertheless, issues relating to recognition accuracy remain
and it is critical to place a handwriting touchpad in a location that facilitates the use of a driver’s preferred hand (Burnett et al., 2005).

The difficulties for complex interactions with vehicle navigation systems are considered to be so significant that many authors believe that systems should disable “overly demanding” functionality when the vehicle is in motion (e.g., by “greying out” options when the vehicle is moving. Burnett, Summerskill & Porter, 2004; Green, 2003). This is currently a rich area for research, requiring an understanding of (a) what is meant by “overly demanding,” (b) establishing valid/reliable metrics for the assessment of demand and finally, (c) deciding where to put limits on acceptability (Burnett et al., 2004).

**Underload for Vehicle Navigation Systems**

In contrast with the overload perspective, over the last five years some researchers have viewed navigation systems as a form of automation, where underload issues become central. Vehicle navigation systems calculate a route for a driver according to pre-defined algorithms and then present filtered information, often via visual and auditory instructions. Two related concerns are emerging as important research questions, of particular relevance to user-interfaces which place a reliance on turn-by-turn guidance.

Firstly, it has been noted that there may be a poor calibration in the perceived versus objective reliability of in-car computing systems (Lee & See, 2004). This is of relevance as a navigation system (particularly the underlying digital map) that is unlikely ever to be 100 percent reliable. Nevertheless, drivers, largely based on their accumulated experience, may believe this to be the case. In certain situations, such overtrust in a system (commonly referred to as complacency) may lead to drivers following inappropriate routes and potentially making dangerous decisions, for instance, turning the wrong way down a one-way street. There is plenty of anecdotal evidence for such behavior in the popular press (e.g., http://www.timesonline.co.uk/article/0,,2-2142179,00.html, September 2006). Recently, research has replicated the effect in a simulated environment and indicated that there are considerable individual differences in the likelihood of a driver showing a complacency effect (Forbes & Burnett, 2007). Further research is considering what role the extended user-interface (training procedures, manuals, marketing information) can have in reducing complacency effects.

Secondly, drivers who use vehicle navigation systems may not develop a strong mental representation of the environments in which they travel, commonly referred to as a cognitive map. It has been stressed that traditional methods (e.g., using a paper map) require drivers to be active in the navigation task (route planning and following. Jackson, 1998; Burnett and Lee, 2005). Whilst the demands (particularly the cognitive demands) can initially be high, drivers who are engaged are able to develop landmark, then route knowledge, ultimately progressing to a map-like mental understanding (survey knowledge). Such a well-developed cognitive map means that drivers are able to navigate independent of any external source of information. Empirical research in this area has shown that drivers using current forms of user-interface for vehicle navigation system do indeed experience reduced environmental knowledge in relation to drivers using traditional methods (Burnett & Lee, 2005; Jackson, 1998). A key research question here is how user-interfaces can be developed which balance the need for low demands (workload) whilst simultaneously aiding drivers in developing a well formed cognitive map (Burnett & Lee, 2005).

**FUTURE TRENDS AND CONCLUSION**

The incessant growth in the use of cars and worries about road safety have led car manufacturers...
Designing and Evaluating In-Car User-Interfaces

to offer more intelligent cars providing a range of novel functions to drivers. Moreover, existing mobile technologies such as PDAs, MP3 players, mobile phones, and so on, are increasingly being used within cars, as drivers seek to be more productive and to enjoy the time spent in their vehicles.

All of these computing-based systems offer potential benefits to drivers. This chapter has focused on some key design issues for user-interfaces from the perspective of the individual driver. However, as systems become commonplace within vehicles, there are fundamental conflicts to resolve between the requirements of an individual versus the overall traffic system. In this respect, the design of an in-car computing user-interface will be a critical consideration. As an example scenario, one can envisage many drivers using information systems providing the same information at the same time. Such a situation may lead to a range of problems, for instance the use of roads not designed for high volumes of traffic. Clearly, there is a need for overall management and an understanding of the impact that specific styles of user-interface will have on driver behavior.

A second broad issue for research concerns the interaction between multiple systems. This chapter has introduced the overload and underload concepts and discussed them in turn relating them to different individual systems. It is highly likely that in the short to medium term, overload will be given a prominent position in research and development work, whereas underload will emerge as an increasingly important topic in the medium to long term. However, this singular view neglects the fact that information and control-based systems are likely to be used together in a vehicle. Clearly, there will be various interaction effects for researchers to investigate. Moreover, there is a fundamental need to find the right balance between the two extremes of overload and underload. As noted by Dewar (2002, p. 330), “humans operate best at an optimal level of arousal, and either too much or too little workload can be detrimental to performance.”

The development of suitable methods for designing and evaluating in-car computing user-interfaces will continue to be an important research topic. Reliable and valid methods are required which are accepted within industry. A key motivation will be to establish ‘quick and dirty’ methods (and associated metrics) enabling designers to understand the likely demands of their user-interfaces early in the design process when very rudimentary prototypes are available. A further critical requirement is for “benchmarking,” that is, establishing a point of reference from which user-interfaces can be compared or assessed. Such benchmarks will be of particular benefit when identifying user-interface designs that are considered acceptable or unacceptable, particularly from a safety perspective.

**KEY TERMS**

**Driver Distraction:** Occurs when there is a delay by the driver in the recognition of information necessary to safely maintain the lateral and longitudinal control of the vehicle. Distraction may arise due to some event, activity, object or person, within or outside the vehicle that compels or tends to induce the driver’s shifting attention away from fundamental driving tasks. Distraction may compromise the driver’s auditory, biomechanical, cognitive or visual faculties, or combinations thereof (Pettitt & Burnett, 2005).

**Driving Simulators:** Provide a safe, controlled and cost-effective virtual environment in which research and training issues related to driving can be considered. Simulators vary considerably in their fidelity (i.e., the extent to which they replicate aspects of real driving).

**In-Car Computing Systems:** Provide information to support the driving task or control some aspect/s of the driving task. In-car computing systems may also provide information and/or services that are unrelated to driving.

**Keystroke Level Model:** Is an established HCI method used to predict expert’s task times with a user-interface. It can be used with in-car user-interfaces to predict static task time, that is, the time taken to achieve tasks in a stationary vehicle. Recently, the KLM has been extended to predict visual demand measures related to the occlusion protocol.

**Overload:** (Due to in-car computing systems) occurs when a driver’s information processing resources are overwhelmed and performance on primary driving tasks inevitably suffers.

**Underload:** (Due to in-car computing systems) occurs when automation of core driving tasks (such as steering, braking, etc.) has led to a situation in which driving performance has deteriorated. This may have arisen because the driver has reduced awareness of other road users, has changed their behavior in negative ways or has inferior skills/knowledge in driving.

**The Occlusion Protocol:** Is a user trial method used in the design and evaluation of in-car user-interfaces. Participants typically wear LCD glasses which restrict the visual experience by only enabling short (e.g., 1.5 seconds) chunks of visual attention with an in-car user interface. Measures related to the visual demand of an interface can be established.

Chapter 2.12
The Semiotics of Smart Appliances and Pervasive Computing

Peter Bøgh Andersen
University of Aarhus, Denmark

Martin Brynskov
Center for Interactive Spaces, University of Aarhus, Denmark

ABSTRACT

This chapter presents digital habitats, a conceptual and methodological framework for analyzing and designing smart appliances in the context of pervasive computing. The concrete topic is a project in pervasive gaming for children. The framework consists of a set of theoretical concepts supplemented by diagrams for representing semiformal models. We give a short overview of selected theories of play and gaming and apply the framework to an implemented simple pervasive game. Finally, we use the framework in a constructive manner to produce a concrete design of a new game. The result is discussed and compared to other approaches. The main points are the following: (a) it can describe communicative as well as material acts plus the way they hang together; (b) it provides an explicit link between human activities and their spatial context; (c) it has an explicit dynamic model that precisely describes the conditions for executing actions; and (d) it offers a typology of participant roles based on linguistic theory, which supports design processes.

INTRODUCTION

In this chapter, we will present an approach to analysis and design of computing systems that transcends the boundaries of traditional office computer systems such as PCs and laptops. These transcending systems are called ambient, ubiquitous, or pervasive computing systems, and they pose new challenges to the way we understand, analyze, and design information technology. With such systems, computing power spreads from dedicated computing hardware into other artifacts and places, both at the workplace and
in everyday life. Microcontrollers, sensors, and actuators have been embedded in machines for decades, but the functionality was tied closely to the artefact in which it was embedded (e.g., a washing machine or the side mirror of a car), and therefore, the computational “smartness” was not foregrounded in itself. Two factors have changed this: (a) the increasing flexibility and computing power of smaller-scale devices, and (b) the wireless networking capabilities and structured exchange of information. In this world of smartphones, GPS (location tracking), and software agents, we need concepts to communicate about human needs and activities as well as technical infrastructures. Digital habitats is a suggestion for such a framework. In our presentation, we focus on fun and games, but the framework originally was conceived in a workplace setting.

“On the Concept of Intelligence” discusses the concept of intelligence and concludes that the everyday use of the concept applies to a disposition to act in a certain way in a network of other actors and artefacts. To be intelligent is to fill out Agent roles appropriately in activities conducted by such networks.

The habitat concept defines the framework we use. On the one hand, it defines activities in terms of roles, participants, actions, and glue binding participants to roles. The well-known automatic door opener is used as an example. On the other hand, it offers a maplike representation that ties activities to physical and informational spaces and describes the various types of interplay between physical and informational space. This is particularly relevant to pervasive computing, since pervasive computing is characterized by being distributed in physical space and by overlaying physical space with digital information.

In “Play and Games,” we give a short overview of theories of play and gaming. In “Designing Pervasive Games,” we adapt the framework to the domain of games and describe an implemented simple pervasive game called StarCatcher. “The Bogeyman” puts all the ends together in a concrete design of the game Bogeyman that elaborates on StarCatcher by drawing on the presented theory. “Related Work” compares this chapter to related fields, and the conclusion summarizes the advantages of the present approach, as we see it.

**ON THE CONCEPT OF INTELLIGENCE**

The first issue that must be discussed is what *smart* and *intelligent* mean.

**Intelligence**

Since there is no universally accepted definition of intelligence (Roth & Dicke, 2005), we accept Gilbert Ryle’s (1970) claim that these words denote (a) the manner in which an action is performed and (b) a prediction about the way other actions are performed. In this case, intelligent does not denote a special mental process that is the cause of the action but rather a disposition generally to act in a certain manner. What is intelligent depends upon the circumstances but often involves features such as: the action achieves its goal, it does not contain superfluous steps, it economizes with resources, it does not destroy or hurt participants, it is an innovative way of solving a difficult problem, and so forth.

This definition is similar to a prevalent view in contemporary cognitive science, that “mental or behavioral *flexibility* is a good measure of intelligence, resulting in the appearance of novel solutions that are not part of the animal’s normal repertoire” (Roth & Dick, 2005, 250). We choose to focus on the behavioral aspect and, thus, preclude ourselves from making inferences about neuroanatomy or mental mechanisms. On the other hand, this choice to focus strictly on behavior allows us to use the word about humans as well as artifacts without committing ourselves to philosophical doctrines about the nature of the mind (see Dennett, 1991).
The Semiotics of Smart Appliances and Pervasive Computing

If intelligence denotes a disposition to act in a certain way, then it follows that its unsophisticated and immediate reference is to networks of actors, instruments and objects. The reason is quite simply that human action normally is mediated by an instrument and directed toward an object. These elements form a network, and it is such networks that we can immediately call intelligent or smart. There will often be a next analytical step in which we ascribe the main honor to one or more of the participants in the network: one of the actors, tools, or objects may be seen as the main contributor.

Networks of Stupidity

This analysis is easier to verify with negative predicates such as negligence, stupidity, and inability. For example, accident reports must point to a participant that is guilty of the accident in order to suggest future remedies against the type of accident and because of insurance issues. Although accidents are mostly caused by a particular configuration of participants in the network, the report must point out the weak link in the chain. However, this is often difficult and a matter of interpretation.

Here is an example, due to PhD student Thomas Koester: a ferry was fitted with a system that compensated the heeling of the boat by moving water in the ballast tanks. The system had a manual and an automatic mode, but sometimes it would unexpectedly go from automatic to manual mode. The mode change was displayed on the bridge and in a closed locker on the deck. The accident occurred when the deck crew was emptying the deck for its cargo of trucks and cars. When cargo is removed from one side of the ship, it will heel, and the system is supposed to compensate; in this case, it had switched to manual. The result was that the heeling was more than six degrees, and the ramp was damaged. Who was to blame? The crew? It knew about the fault; should they have opened the locker and checked the mode regularly? But then the disembarkation would have gone more slowly. The manufacturer? The system obviously should not be allowed to switch to manual by itself. The ship owner? He could have counteracted the fault by mounting a warning system on the deck, informing the deck crew of the mode shift.

The fault is clearly due to the whole network: a faulty system + missing indications of the error + lack of attention in the crew. It is a practical and political matter, not a philosophical issue, to decide on a remedy: correcting the mode error, mounting a warning light on the deck, or changing the operation procedures.

The importance of networks vis à vis individual actors has been emphasized in the actor network theory (Latour, 1994, 1999; Law, 1987). For example, power is a predicate that pertains to an actor’s position in a network, not to the individual actor.

The example illustrates the point made previously: predicates such as intelligent, smart, sloppy, inefficient, and so forth are in the first place predicates of networks, not of their parts. Only analytically can one of its participants be singled out as the main factor, and this choice depends upon the countermeasures that are considered feasible and desirable.

The same line of reasoning can be applied to intelligence. The IBM chess program Deep Blue beat grandmaster Kasparov on May 4, 1997. Therefore, there is an intelligent network of actors comprising at least the following participants: the developers, the chess literature they used, the system, and the operator. But which participant should be picked as the winner of the match? It is as difficult to decide as in the accident case, but it was the development team behind Deep Blue that took home the $700,000 first prize. Thus, in practice, the development team was singled out as the intelligent part of the network.
Intelligent Technology

If we are to single out one participant of an intelligently conducted activity, it must be because its contribution is particularly conspicuous. How do we decide this? One way is a simple substitution: if we keep the chain constant and replace one participant, does the performance of the chain become more or less intelligent? If the chain performs less intelligently, we may tentatively attribute intelligence to this part of the chain.

From these arguments follows a definition of smart/intelligent technology:

1. Intelligent technology is a kind of technology that is able to contribute positively to activities whose manner of performance we will intuitively call intelligent.

   In the following, we incorporate this definition in a broader framework, which we call a habitat. The habitat concept is a general attempt to link networks of activities and actors to physical space on the one hand and signs and sign usage on the other hand.

THE HABITAT CONCEPT

The habitat concept was elaborated in the research group Frameworks for Understanding Software Systems (Andersen & Nowack, 2004; Brynskov & Andersen, 2004; May & Kristensen, 2003). The purpose of the research was to devise a methodology that is better suited for handling context-sensitive pervasive computing than are traditional ones. Traditional object-oriented modeling methods (Mathiassen, Munk-Madsen, Nielsen, & Stage, 2001) are characterized by two features: (a) they model conceptual structures while the physical system represented by these models is absent in the method, and (b) the physical location of the software components is postponed to the last implementation phase (Andersen & Nowack, 2002). This is a problem in context-sensitive pervasive computing, because one of its possibilities is the use sensors to collect information about physical objects located in the spatial or temporal vicinity of the physical device where the software resides. Therefore, we need to coin concepts for the information available in the vicinity of the physical device and for the physical objects referred to by its software model. The former concept is called the access area; it denotes the locations from where sensors can access information; the latter is called the reference area and denotes the location of the objects referred to by the software model. Furthermore, a description of information is incomplete if we do not specify its use (i.e., what activities is the information used for?). Therefore, we need to enter the notion of activities into our framework. Finally, we are interested in systems that are sensitive to their physical surroundings, which means that our third component must be space. We are interested in physical spaces that are designed or have evolved to support a delimited set of human activities. This is true for an overwhelming number of the spaces in which we live daily: private houses, airports, hospitals, railroad stations, road networks, and so forth. We have chosen the term habitat to denote a physical space that is designed to support some set of activities and that provides access to information about objects relevant to the activities (Brynskov & Andersen, 2004).

2. A habitat is a chunk of space-time that is designed or has evolved to support a delimited set of activities by offering physical artifacts and information sources useful for conducting the activities.

   From this definition, it follows that a habitat should be characterized along three dimensions:

3. The physical habitat: The physical layout and boundaries of the habitat plus the available physical artifacts.
4. **The informational habitat:** The signs available (access and reference area) to participants in the activities (digital and nondigital signs).

5. **The pragmatic habitat:** The action affordances offered by the habitat, the macro-roles, and the role-requirements of the participants.

The contribution of the present chapter is threefold: (a) it explores the usefulness of the habitat concept in the domain of pervasive games; (b) it presents a framework for describing communicative and material activities and the way they interact; and (c) it presents a notion of intelligent or smart technology that is consistent with the framework. The chapter mostly draws on semiotic and linguistic theory, and our basic understanding of the habitat concept is well-captured in Peirce’s semiotic triangle (Figure 1). The space itself and its manufactured representations (e.g., signposts and electronic displays) are representamens; the interpretant of these signs is the activities associated to the habitat, and the object is the phenomena inside the reference area (i.e., things or events that are relevant to the activities).

**Activities**

In order to use definition (1) for design purposes, we need a general functional definition of activities, and a set of context-dependent definitions of what criteria intelligent activities must meet in various domains. The general definition is given in this section. The game-specific adaptation is presented in the section “Applying the Theory to Games.”

**Goal, Roles, Participants, and Actions**

As in the case of intelligence, we adapt a functional view of activities (Andersen, 2004a, 2004b, 2005; Bødker & Andersen, 2005; Brynskov & Andersen, 2004). The conceptual framework consists of roles, participants, actions, and activities. Activities consist of actions subsumed under a shared goal, and participants play roles in relation to actions and activities.

At the action level, we use traditional linguistic semantic roles like agent, theme, instrument, beneficiary, source, destination, time, place, direction, and so forth (see Fillmore, 1968, 1977; Blake, 2001). At the activity level, we use macro roles like librarian/borrower, customer/clerk, lawyer/client, judge/defendant, and so forth. The macro roles are defined by the semantic roles that participants can play in actions: thus, a Judge is the Agent of actions like planning the sessions of the court, considering the judgment, giving a verdict, sentencing, and so forth. This is the method used in the classical work on narratology (Propp, 1968).

In addition to specifying actions, roles, and activities, we need to specify the goal of the activity. We distinguish between four types: creating, destroying, preventing, and maintaining a state (Lind, 1994).

Not all participants are equally qualified to play these roles; a role requires its filler to possess the requisite incentives and qualifications in order for it to contribute in an intelligent and competent manner. Incentives include intentions, desires, and obligations; qualifications cover the relevant abilities, rights, and knowledge. Sometimes we
will refer to these qualifications as a lump of glue that binds a participant to a role.

Some of these requirements are realized differently in humans and nonhumans. For example, intentions are implemented as negative feedback loops in automatic systems like thermostats that aim at keeping a certain process variable (e.g., the heat) locked at a certain set-point. Its goal is to maintain the process variable at the set-point. In software agents (Russell & Norvig, 2003), intentions often are implemented as some kind of means/end structure along with a planning and execution algorithm. The goal often will be to create a certain state, but in order to do so, the algorithm will have to maintain other states (protected states) and prevent others (forbidden states).

According to the approach outlined previously, we should not necessarily ask whether this implementation resembles the way humans make and execute plans. Instead, we should ask for qualifications: to which degree is the behavior of the automatic system suited for playing its assigned roles in the activity? The same goes for knowledge: there are many types of knowledge representations (predicate calculus, semantic networks, frame systems, conceptual graphs, and neural networks), but for the present purpose, it is not interesting whether humans use something comparable but only to which degree the system component using these methods is able to play its allotted role. The viewpoint, thus, is strictly behavioral.

In this chapter, we will concentrate on cooperative activities involving humans, intelligent systems, and dumb artefacts. Since the activity is cooperative, the following requirements of intelligent agents are important:

6. The agent should have intentions to act that are understandable to the others (comprehensibility);
7. Agents should display their intentions and actions in a way that is accessible to the other participants (accessibility);
8. Agents should be able to perceive and manipulate the attention-focus of their colleagues and adapt their own actions accordingly (joint attention);
9. Agents should be able to enter and leave the activity (intermittent participation).

Applied to mechanical agents, comprehensibility (6) means that they only should form plans that are understandable to their human and nonhuman colleagues. Understandable algorithms have a higher priority than cunning ones, but there is a tradeoff between intelligibility and efficiency.

The intentions of the agent should be signaled to the other participants in a way that allows them to reliably infer intentions from behavior (accessibility, 7). In other words, there is a mutual commitment to signal the truth, the whole truth, and nothing but the truth in the least complicated manner (equivalent to the so-called Gricean maxims [Grice, 1975] from the pragmatics of natural language). On the other hand, once the deliberate representation of intentions has been introduced, it is possible to misuse it to lie about intentions as well.

Attention is intentionally directed perception (Gibson & Rader, 1979; Tomasello, 1995). Joint or shared attention (8) is necessary for cooperation: If I cannot see what my colleague is concentrating on, I cannot collaborate with him or her. However, shared attention is more than just looking at the same object or detecting gaze direction; it is the mutual understanding between two intentional agents that they are, indeed, intentional agents (Tomasello, 1995) (see Dennett’s, 1987, The Intentional Stance). In order for me to share a goal-directed activity with somebody, I not only must be sure that the other participants have their minds focused on the objects or topics I think of myself, but all participants also must share the fundamental assumption that activities can be goal-directed and that they can be coordinated by detecting and manipulating attention. In fact, shared attention is a constituent factor in cultural
Humans share attention all the time, beginning near the end of their first year of life as a result of a constellation of emerging social behaviors (e.g., communicative gestures, imitation, social referencing) (see Tomasello, 1995). We can read or infer and, therefore, continuously follow and manipulate each other’s focus of attention (and thereby intention) throughout a joint activity. This interpreted focus is a common anchor point without which two persons would drift away from each other—mentally and physically—instead of staying focused on the same subject matter. They would be solipsist nomads.

Intermittent participation (9) means that participants must be able to leave and enter the network without its breaking down. Much pervasive technology, including games, must allow participants to enter and leave without notice. For example, a door opener would be unusable if the pedestrian were to type in complicated commands preparing the door for the event before walking through the door and signing off after the passage. The ferry system in Networks of Stupidity was not sufficiently robust to allow the mechanical agent to leave the network without notice; the network broke down and damaged the ramp.

Joint attention and intermittent participation are also important in our concrete topic: children’s games. When children play, it is important for them to keep track of the other’s focus. Children gradually develop this sense of playing or doing things together as opposed to just doing things in parallel. At the age of two, they have all the prerequisites for joint attention (Kaplan & Hafner, 2004), and they continue to develop still more complex social interaction based on this fundamental competence. Also, children enter and leave activities very often (i.e., their participation is intermittent and highly dependent on the environment). They have to go and eat, must go outside, or one participant is picked up by his parents.

An example of a game that supports intermittent participation is LEGO Star Wars (www.lego.com/starwars), which allows players to join and leave a game in progress so that a parent can step in and help a child but leave again without having to play the entire game. When a player leaves, the character continues as an independent agent controlled by the software (at least one player must be controlled by a human, however; otherwise, the game ends). Massively Multiplayer Online Games (MMOGs) (e.g., World of Warcraft [www.worldofwarcraft.com]) are another example of games built around intermittent participation. Mobile MMOGs exist, too, and are called 3MOGs (e.g., Undercover 2: Merc Wars [www.undercover2.com]). Often, children can be seen not only as mobile but also as nomadic, because they are dependent on the resources and partners offered by the environment (see the following section). In this case, the proximate environment has a marked influence on their patterns of play (Brynskov, Christensen, Ludvigsen, Collins, & Grønbæk, 2005).

The problem of sharing attention between humans and machines is that machines do not have the ability to read attention, let alone intentional stance (see, however, Kaplan & Hafner, 2004). In the ferry incident, one of the problems was also the lack of joint attention. The automatic pump system switched to manual operation without monitoring whether this important change was brought to the attention of the crew. The crew, on the other hand, could not monitor the attention of the pump system and, therefore, failed to realize that they were supposed to operate the pumps manually. Thus, intermittent participation seems to require joint attention.

People use language to a large extent to signal their focus of attention. With machines in the loop, this is not possible, not because computers cannot produce or parse speech at all (they can to some extent), but because their underlying representation of attention and states do not map easily onto their human partner’s. This is because
the semantics of a language is not context-free but grounded in experience. Humans seem to take the other’s perspective by mapping observations onto their own nervous system in a kind of simulation. Therefore, joint attention presupposes understandable algorithms.

If we still want humans and machines to share attention during activities, we have two options:

- We can try to develop epigenetic artificial intelligence that can learn to share attention by means of contextual grounding, imitating human cognition (although it is still an open question how exactly to achieve this) (see Steels, 2003; Kaplan & Hafner, 2004), or
- We can try to create a fixed, hardcoded, and more simplistic common ground where both humans and machines can read and interpret behaviors.

We choose the latter, and one of the methods is to design comprehensible algorithms so that there is something for the human participants to share. As a consequence, one might say that the burden of flexibility, to a large extent, is put on the shoulders of the human participants.

The challenge of handling attention focus and intermittent participation is not at all new in human-computer interaction (HCI), especially in the field of computer-supported cooperative work (CSCW) (Bardram & Hansen, 2004). There is a difference, though, in signaling an application’s states and functions as a tool or medium, as is the traditional case in HCI, or a person’s availability in CSCW, to signaling an agent’s states. The difference is whether we attempt to represent intentions (Tomasello, 1995). Attentive agents and calm systems that work in a sort of symbiosis with their owner and sense or guess his or her intentions is an old idea (Licklider, 1960; Weiser & Brown, 1995), and it is still being pursued (Maes, 1994; Maglio & Campbell, 2003). As already mentioned, participants in our framework are glued to their roles not only by intentions but also by desires, abilities, rights, obligations, and knowledge, which also, to a higher or lesser degree, indicate intentions. Therefore, a minimal requirement is to signal these binders not only in a form that humans can interpret but also the other way around. We see play as an interesting case, since this is an important part of the situations in which children learn the intricacies of the semiotics of behavior.

### Door Openers

In this section, we illustrate the concepts used to model activities by a widespread technology; namely door openers. In addition, we offer some simple diagramming techniques. Door openers are good examples because they involve networks of humans and nonhumans, and nonhumans play an Agent role in the sense that they initiate and monitor activities.

The activity concept is the one described previously. We use a diagram consisting of actions, and we highlight the relations between the actions by graphical means. Two actions can be connected by arrows signifying dependencies

![Door Openers](image)

**Figure 2. Automatic door opener in shopping mall**
between participating in the two actions. The rules are as follows:

10. An activity is executed if all participants are able to fulfill their roles to some degree and if the Agent filler is strongly obligated and/or strongly desires to fulfill his or her role. In the game described in “The Bogeyman” section, desires are created by application of dissonance theory (Eskola, 1973), whereas ability is created by the participant’s location. Whenever the necessary participants are assembled in the same place, the activity is enabled.

11. If something successfully participates as role A in executing action X, then its intentions, desire, abilities, rights, obligations, and/or knowledge (its glue) to participate as role B in action Y are changed.

We shall use various ways to diagram these notions (a discussion of diagramming techniques can be found in Andersen, 2004b). Figure 3 shows an ordinary door opener from a shopping mall. The dependency between actions is shown by arrows annotated by the glue dimension affected. The participants involved are shown in boldface.

The activity contains five actions that are connected as follows: when a person walks toward the door in order to get in, the door opener is required to open; when it does, it becomes able to function as a passage for persons passing the doorway but also for heat disappearing. When it closes, it loses these abilities. The goal of the activity is letting people in through the door while preventing heat from disappearing. Since the two goals are contradictory, we must dissolve the contradiction by unfolding it in time. Therefore, when the door opens, it becomes obligated to close after, say, 30 seconds.

In the game-specifications, we use a simplified version of the diagram in Figure 3. The simplified diagram is on a high level of abstraction, displaying only the essence of the game.

The abstraction is made in the following way:

12. The participants, roles, and glue changes responsible for the dependency between the actions are stripped away.

Figure 3. The activity of door-opening focusing on the door participant. Obl = obligation, abil = ability. ‘+’ means increases, ‘-’ means decreases
13. Abilities and rights are merged under the heading *possibility* and represented by a single-headed arrow \(\rightarrow\).

14. Desire and obligation are merged under the heading *necessity* and represented by a double headed arrow \(\leftrightarrow\).

15. Inability or prohibitions are merged as *impossibility* and represented by \(\#\).

The behavior of the door opener now looks as shown in Figure 4.

The reason for these formal abridgements is that diagram design is a tradeoff between precision and overview. The reader should be able to grasp immediately the possible paths of the story by reading the diagram. However, there is still an underlying detailed semantics in which participants, roles, glue, and glue changes are specified. They are just not shown in the diagram.

The previous notations highlight the interdependencies between actions but do not provide a clear picture of the relation between activities and space. Such relations are important when we design context-sensitive, pervasive technology, and therefore, we introduce a maplike notation in the next section. It associates activities to a physical space, if the space plays the role of location in the activity.

**Habitats**

In pervasive computing, the physical space and its relations to the informational space becomes important. Therefore, we need a diagram that highlights the spatial properties of activities and networks, in opposition to the previous section in which we highlighted the relations between actions.

Figure 5 shows a diagram that codes the spatial participants graphically and tones down relations between actions. We have selected the spatial participants (i.e., spaces that participate in the Location role of the activities, spatial participants filling the location roles are called *habitats*. We have shown two habitats: the shopping mall and the entrance. To each habitat is associated the actions that can be performed there: selling and paying in the shopping mall, and walking through doors at the entrance. In addition, we have represented the signs involved in terms of (a) the area from where they can be accessed (the access area) and (b) the area containing the object denoted (the reference area). Both areas are shown by means...
of dashed polygons, and an arrow points from access to reference area. Thus, the door opener has access to the areas inside and outside the door. The arrows are decorated by the main signal path. Sensors often transmit and receive signals in two directions. For example, radar sends out radio waves and records their echo. The outgoing waves are only a means for receiving the ingoing echo. Therefore, the main signal path in radar is from reference to access area, which is also true in the door-opener case.

We distinguish between relative and absolute references. The difference is that if the access area of relative references moves in time or space, the reference area moves, too. This is not the case with absolute references. The reference of the door opener is relative, since if we move the door opener, it will refer to the new environment in which it is placed. Transponders, RFID-tags, and radars create relative references. The distinction also shows up in language, where the so-called deictic words (here, now, me, you) have references relative to the speaker. Compare the two sentences: The Second World War ended in 1945 and The Second World War ends now. The former does not change meaning if it is uttered in year 2000, whereas the latter becomes false if uttered in that year.

To each habitat is associated half-baked actions that can be performed there—the *affordances* (Gibson, 1986) of the habitat. In the following, “#” means that the role is instantiated, whereas a type indication such as pedestrian means that the role can be filled by a specific type of participant. Pedestrian walks through #door thus means that the Location role is instantiated by the particular door and fixed, while the Agent role can be filled by any pedestrian. Fully instantiated actions are created by unifying the action possibilities of the participants with the affordances of the habitat. For example, #smith can walk through doors + pedestrians can walk through #door unifies to #smith can walk through #door, because #smith is a pedestrian and #door is a door. If #smith was not a pedestrian but a car, or if #door was not a door but a wall, unification would be impossible, and no action could be instantiated. There are many ways to implement instantiations. In (10), the “Activities” section, we suggested a particular way of doing it: shared location gives the participants the ability to instantiate roles in the actions, while desire gives a participant the incentive to instantiate the agent role.

This way of combining abilities from agent and environment is useful in agent design, as argued by Cabri, Ferrari, and Zambonelli (2004),

---

**Figure 5. Shopping mall and entrance.** #door means “an instance of the class of"
who also uses a role-based architecture. We shall term it contextual execution. The term means that an execution of an action consists of pieces, some of which originate from the participant, while others come from the habitat. This enables participants to act flexibly in different contexts without having to remember the exact details of each particular context.

The notion of half-baked actions (Andersen, 2004c) reflects the idea that we normally never start from scratch when we act. We know that specific participants normally are useful for the purpose we want to accomplish, and we try them out first. To take the door opener example, if we want to enter a room, we do not start with the isolated verb enter and spend time reflecting which participants it should have. Our point of departure is enter through #door, where the direction case is instantiated by a specific door we can see. Only if the door is locked may we begin considering the windows and the chimney. Another argument is that isolated verbs do not allow predictions: drinking milk, beer, and cyanide has quite different consequences.

In this method, all actions are bound to a certain physical habitat, and, indeed, many actions work in this way. We do need to be inside the airport to embark on an airplane. But what about the planning of the travel? Do we have to be in Portugal in order to plan the travel from the airport to the hotel in Lisbon? No, of course not. Some activities, such as planning, should not be and are not bound to specific locations. Instead, we imagine how things are in Lisbon and simulate the remaining part of the travel in our minds (or on a computer, or let the travel agency take care of the problem). This means that we need the concept of fictive habitats: habitats we imagine and in which we can test solutions without being there in reality. Fiction in general enables us to enjoy living in fictive habitats for a delimited period of time, and therefore, we shall need the concept in “Designing Pervasive Games” and “The Bogeyman,” where we address the question of designing pervasive games for children (on the logic of fictive worlds (see Ryan, 1991). Pervasive games thrive on the interplay between actual and fictive habitats, as we shall see presently.

**PLAY AND GAMES**

The preceding conceptual framework has mostly been used for analytical purposes or for instrumental design topics like brain surgery; evacuation procedures on ships; and pervasive applications in shopping malls, airports, and hospitals (Andersen, 2005; Andersen & Nowack, 2002, 2004; Brynskov & Andersen, 2004; Haase, Musaeus, & Boisen, 2004; Kristensen, 2002, 2003; May & Kristensen, 2003; May, Kristensen, & Nowack, 2001).

Designing technology for playful activities is very different from designing tools for instrumental activities. It is not necessarily the most efficient solution that is the best solution. The user should have fun—and fun is hard to predict and design. Thus, playful activities often are not goal-directed, at least in the sense that the goal may be hard to define or quantify, and the activity may be enjoyable for its own sake (see Csikszentmihalyi’s, 1990, concept of flow).

In the rest of the chapter, we shall test our framework in a design context. In particular, we shall explore whether it yields creative ideas for designing pervasive technology for children’s play. The project called Nomadic Play in Mixed Environments is a part of the Center for Interactive Spaces at the University of Aarhus.

The notion of nomadic play is different from mobile play. Mobile indicates independence of physical location (i.e., activities are enabled, and resources are available regardless of the user’s location). For example, a mobile phone may allow a child riding a bus to play a game, check e-mail, or use instant messaging. Nomadic, on the other hand, indicates dependence of physical location. The analogy is nomads traveling through the desert, being dependent upon oases and family
networks. In a similar fashion, nomadic users are dependent upon, or take advantage of, resources and services that are made available by the environment, including other people’s devices (peer-to-peer). Thus, nomadic play indicates a playful use of smart appliances and pervasive computing systems that could not occur if the child was not at a certain location (e.g., at a club or at home) that offers certain services (e.g., a home game server or media center) to a certain group of people (e.g., friends of the house). One could argue that certain features of mobile systems are also nomadic in nature (e.g., the coverage of mobile phone networks, but we restrict the term nomadic to systems that are more local in the physical sense and, thus, are designed to support a more focused set of human activities.

**Theories of Play and Gaming**

Children’s play has mostly been treated in developmental psychology (Piaget, 1962; Sutton-Smith, 1979; Vygotsky, 1976) and in the context of game design (Salen & Zimmerman, 2004). Here, we adopt the view that play is the search for fun. To be a bit more specific, play is a focused but internally motivated activity without serious consequences. It may not have a goal outside itself other than it keeps a child occupied in a way that allows it to gain experience in the world, both physically and socially. From this perspective, play could be seen (by adults) as training and preparation for adulthood, whether structured or not. The search for fun is the fuel that drives the activity. Thus, learning may be considered play, as long as the internal motivation is high, because it is fun.

Playing a game can be seen as a special case of ludic activities, which, in turn, are a part of being playful (Salen & Zimmerman, 2004). A game can be defined in many ways, and there are plenty of suggestions from which to choose. Koster (2005) lists the following from academia: Roger Callois’ an “activity which is ... voluntary ... uncertain, unproductive, governed by rules, make-believe”;

Johan Huizinga’s “free activity ... outside ‘ordinary’ life ...”; and Jesper Juul’s (2005):

*A game is (1) a rule-based formal system with (2) a variable and quantifiable outcome, where (3) the different outcomes are assigned different values, (4) the player exerts effort in order to influence the outcome, (5) the player feels attached to the outcome, and (6) the consequences of the activity are optional and negotiable.* (Juul, 2005, p. 3)

We distinguish between two types of playful activities: playing and gaming. A game has fixed rules and a quantifiable outcome (a clear goal), whereas play has ad hoc negotiable rules and a fuzzy outcome. A game can be embedded in play (see Juul’s point about the optional and negotiable consequences of a game). Both types of activities should be fun.

An important distinction is that between emergent games and games of progression (Juul, 2005). In the former, the game is defined by a small number of simple rules governing a possibly large number of human or nonhuman participants. An emergent game can be played many times, since each round is different. Emergent games invite planning and strategic thinking. Games of progression are defined by a more or less fixed sequence of events and often tell an elaborate story. Like novels and films, they seldom can be played more than once.

Our two games are games of emergence, but in *Bogeyman*, we have tried to add narrative traits.

**Applying the Theory to Games**

This section adapts the concepts presented previously to the special case of games. In this section, we consider games in general, and in the next section, we focus on pervasive games.

We first show that the glue concept (that binds participants to activities) is useful to characterize games.
The children’s desire motivates them to enter activities (“come and join us; this is fun”) and a lack of desire to leave them (“I am going home because this is boring”). Playthings must create desires in children to assume the Agent role.

*Ability, rights, knowledge and obligations* may regulate participation for human as well as nonhuman participants. An able goal keeper is sure to be enrolled in a soccer game. In the Danish game called The Earth Is Poisonous, it is allowed to tread on furniture but forbidden to step on the floor, because it is poisonous. These tokens of glue may be earned from previous activities, and if they are given a physical shape, they can be exchanged by the children. For example, a child only can participate in secret club activities if he or she has been allowed access to the club and can show his or her membership card.

A child may only get entrance to the club den if he or she knows the secret password. Or abilities may be missing: “You are not allowed to take part because you are stupid.” (One might ask, Who is lacking abilities here?)

Glue like rights and obligations can be distributed: “I’m the president and you must do what I tell you. No, that is silly. Well, then you can be the vice-president and tell Billy what to do.”

Actions can be associated to spaces via the habitat concept. “This is a pirate ship, and the grass is water. You cannot walk on the water. If you do, you drown.” “This chair is a car that can go 200 miles per hour.” “The flagstone is a hole in the Earth, and if you tread on it, you will fall down.”

Games can have different purposes:

- **Creation**: The objective of soccer is to accumulate goals. The goal of exchanging Pokémon cards is to increase one’s collection.
- **Destroying**: The objective of a Star Wars game is to destroy the Death Star. The objective of teasing and mobbing is to destroy the self-confidence of the victim.
- **Preventing**: The objective of a cowboys and Indians play is to prevent the Indians from conquering the fort.
- **Maintaining**: The goal of skipping is to keep the skipping rope moving.

If we focus on pervasive games, the following possibilities present themselves. According to (10), activities can be executed if its role fillers are qualified for the roles and if the Agent filler desires or intends to fill the Agent role. The roles, therefore, are filled by entities that meet the requirements (glue). In the nomadic play scenario, roles are filled by children, artefacts, hardware, software, and locations. Joining and leaving the activity is done on an ad hoc basis, like when children play. At the conceptual level, we do not discriminate between children and software agents. It is the definition of the role at hand that matters. As a consequence, if a software agent meets the requirements to fill a role, it can play it. This also means that a child could fill a role that usually might be played by an artefact or piece of software.

Children and software may compete for filling a role: “I do it” vs. “My mobile phone does it.” More interesting, however, is in-between situations in which child and software together fill a role. Part of the role is automated; part of it is manual. Sometimes a child may be represented by a less capable but sufficient software agent, and agency could be transferred back and forth. Such shifts between manual and automatic control are very common in process control; sometimes the officer of the watch maintains the course, and sometimes the autopilot does it.

A collection of roles that typically go together can be collected in macro roles. These macro roles either could be statically defined, like in the rules of a game, or they could be assigned dynamically, based on the actual history of actions taken by or experienced by the entity (bottom-up role filling). This goes for human as well as nonhuman participants. The latter gives
us interesting opportunities, since the playthings can have a memory that remembers the glue they have earned in previous plays. This is well-known in role-playing games (RPGs). You must earn experience points to become a level-32 wizard. In the extended case, the character can develop behavioral traits and reputation in an emergent fashion, based on previous actions (e.g., by choosing to practice certain skills).

Sharing things is a central part of many activities. We want to be able to share passive objects as well as active or intelligent ones. This also means that pieces of runnable code should be able to migrate live on a variety of different hardware (contextual execution).

The effect is that we get a network, as described previously in actor networks, in which the possibilities are not tied to the entities themselves but rather to the possible roles they can fill in a given set of activities.

DESIGNING PERVERSIVE GAMES

In this and the next section, we use the contextualized concepts previously defined for designing two pervasive games.

The Technology

In the Nomadic Play project, we try to invent new ways of having fun or being cool using digital media, specifically pervasive and ubiquitous computing devices. Those devices are characterized by being small enough to be carried around as other small objects that surround children (e.g., toys, phones, clothes, pencils, books, stones), or they may be embedded in the environment like other resources we know—in playgrounds, computers, blackboards, and furniture. In essence, these new digital artefacts and environments should be designed in a way that allows them to become a natural part of playful activities.

Compared to traditional artefacts, these devices present new opportunities. They can process information, sense the environment via sensors, interact with it physically through actuators, and communicate with other devices through wireless networks (for early thoughts on ubiquitous gaming in the context of construction kits, see Sargent, Resnick, Martin, and Silverman’s, 1996, list of “Twenty Things to Do With a Programmable Brick”). Apart from actually making the technology work, one of the biggest challenges is to find out how activities involving children, artefacts, hardware, and software can be brought to play in a way that feels natural and fun. The digital media should not be a separate distraction from the play, not in the sense that it should be invisible, but rather that it should be an integrated part of the activities. In order to test our ideas, we have begun designing playful activities for children involving pervasive computing.

StarCatcher: A Simple Example

In this section, we describe an existing pervasive game, StarCatcher (Brynskov et al., 2005). In the next section, we use our framework to elaborate on the game by introducing features that are more complex and, hopefully, more entertaining.

StarCatcher is a simple version of Capture the Flag (Figure 6). It can be played by two or three teams in any urban area of approximately 500x500 meters, and the objective is simply to catch a virtual star (Figure 6b). The first team to reach its location and run to its home base wins and become Star Winners, and the game is over. The losers get the Loser Star (Figure 6c). There is also a slightly more complex version: If the team with the star is intercepted by the other team before it reaches the base, it drops the star, and both teams must visit the home base before it can be picked up again.

Technically, each team is equipped with a mobile phone and a GPS unit (Figure 6a). The game software runs as a client on each phone and on a
central server. The clients send their positions to the server, and the server returns the game state. The phone interface is a map of the close proximity of the team (50-m radius) in which each team is represented by a pulsating dot.

The framework described in section “Activities” offers two ways to describe the game: either focusing on (a) relationships between actions or (b) on the habitats. Figures 7 and 8 use the formalism introduced in Activities to diagram the activity Playing StarCatcher. Figure 7 shows the simple version, Figure 8 the elaborated one. The + and - marks represent the desires of the participants: both team A and B strongly desire to win.

As appears from the diagrams, our game specification uses half-baked actions, as argued in The Habitat Concept. For example, in Figure 8, there are three actions with the same verb: “B walks,” “B walks home,” and “B walks with S.” In the game, these variants have quite different consequences and, therefore, are treated as three different actions. If we magnify these actions, they will look as shown in Table 1, but a description at this level of detail will clutter the diagram and make it useless.

Figure 9 shows StarCatcher described as a habitat. The dashed fat rectangle represents a fictive habitat (see section “Habitats” and Andersen, 2004a). The child C can see its surroundings in the actual (the dashed circle) as well as the fictive world (the dashed rectangle). The reference from the actual to the fictive world is relative (section “Habitats”), since the reference area moves as the access area (the child and the mobile phone) moves. Figure 9 is rather abstract, but in the implementation phase, it will be replaced by a map that shows the exact shape of the actual and fictive habitat and the exact shape of the access and reference area. In the figure, we have indicated that the reference area is different in the actual and the
Figure 8. Diagram of the activity Playing StarCatcher (extended version)

Figure 9. The habitats of StarCatcher; C = child. A = Agent role, O = Object
The fictive world. In the actual world, the child can see things within a circle centered in the child; in the fictive world, the access area is rectangular due to the shape of the display.

The fictive habitat contains the avatars of the children and the star. The children, therefore, lead a double existence in the real and the fictive world, while the star and the winning position only exist in the fictive world. They are not marked in the actual world. The same difference is found in the actions: catching the star, walking with the star, and winning are fictive, while meeting the other team and walking around in the city are done in both worlds.

The fictive habitat contains two subhabitats: the area around the star where catching is possible and the home base where winning is possible. The action of catching requires two roles: the child (Agent) and the star (Object). In Figure 9, the agent role and catching the star is empty (shown by the white color), so the action cannot be executed. Only when the child moves (the fat arrow) into the habitat will it be able to participate. This is a graphical way of representing the process of unification described in section “Habitats.” Habitats, thus, are loaded with activities that are triggered when qualified participants move into them. This, in fact, is one of the reasons for mobility work (Bardram & Bossen, 2005; Brynskov, 2004); in hospitals, for example, many activities are bound to specific locations, and nurses, doctors, and patients spend much time just moving physically from one habitat to another in order to fill empty roles in urgent activities that are executed as soon as all necessary participants are assembled.

The example shows that our framework is indeed able to conceptualize essential aspects of the game; the dependencies between the actions and, in particular, the relation between actions and physical environment and the interplay between the actual habitat and the fictive one.

In the following, we will describe a new game, Bogeyman, which is an extension of StarCatcher. The purpose is to find out whether the framework is a good support for creative design and whether it can provide new and entertaining ideas while still modeling relevant elements of complex pervasive gaming.

THE BOGEYMAN

If all we wanted to do was to model locative games as simple as StarCatcher, there would not be much need for a framework. But with the expanding opportunities of pervasive gaming (due to technological evolution and commoditization of pervasive computing systems), a whole range of complex issues arise that make formalized support for development of such systems more and more difficult. We can design more sophisticated games using the dynamic interplay of aspects at different levels (e.g., physical, technological and social) but at the cost of complexity. Addressing this complexity at appropriate levels is an important motivation for developing our framework.

StarCatcher actually was implemented and tested; Bogeyman is an extension of StarCatcher and has not been implemented yet, although we do present a core algorithm of the play. The purpose is to test our framework as a design support tool; does it help produce interesting ideas for an extended game?

Activities and Habitats

Let us start with the first two desiderata: we want the following:

16. An emergent game in which simple interactions between more participants can create surprising and entertaining situations (section “Play and Games”).
17. A better exploitation of the interplay between the real and fictive habitats (section “Starcatcher”).
Desiderata (16) concerns the activities of the game, whereas (17) relates to its real and fictive habitats.

In StarCatcher, there was only one thing to collect: the star. In Bogeyman, the purpose is for the children to collect as much candy as possible and avoid being eaten by the bogeyman. While the star was purely fictive, candy may be fictive or real or both. The Bogeyman game is also set in the city (i.e., an area not especially built for the game). However, to a certain extent it does incorporate physical aspects of the surroundings (e.g., the real sewers of the city, which the fictive mice can enter and leave). When the mice are in the sewers, they are invisible in the fictive world.

There can be from two to 10 kids (single players or teams). The technical setup is basically as in the simple StarCatcher game (mobile phone + GPS), with the addition of Bluetooth interaction with places and artefacts.

The objective of the game is to collect as much candy as possible. The purpose, however, is broader, defined as (a) having fun together and (b) developing relationships between the players.

We want some kind of recognizable narrative macro structure (e.g., built upon Greimas’ schema) (Greimas, 1966). A Subject desires an Object, is helped by Helpers, and opposed by Antagonists. In the game, the kids (Subjects) run around and try to catch candy (Object of desire) without being caught by the bogeyman (Antagonist). Whenever they see a piece of candy, virtual or not, they approach it cautiously. If the bogeyman is hiding close by, he will catch them, strip them of all their candy, and eat them. When this happens, they must return to the home base and be brought back to life again (“spawned”) before they can enter the game again. The kids cannot see whether the bogeyman is near. So, in order to avoid him, the kids can get help from the dogs (Helpers). We want these macro roles to emerge from the action dependencies constituting the game.

The dogs, however, are not necessarily interested in helping the kids. But if they receive a sausage, they acquire a positive attitude to the children’s goals and thus desire to act in a way that supports the children.

The execution of the rules controlling the fictive participants conforms to (10) above: the Agent of the action must desire or be obligated to act, and all participants must be able to do so. This means that (a) the software must create desires in the software Agents that are understandable to the children, (b) that actions are only enabled when all participants are in the same location. (b) will involve a lot of physical and virtual movements, which is desirable for a pervasive game.

For example, if the dog is given a sausage, it desires to chase the bogeyman away. But if there is no bogeyman present, the role of the chasee is empty, and the chase-action cannot be executed. Only when the bogeyman appears and fills the chasee role can the dogs execute the action they desire. Processes involving obligations and desires are clearly fictive, whereas processes involving ability is both real and fictive, since the fictive locations of the software agents must coincide with the real locations of the children.

In the section “Activities,” (6)-(9), we listed four requirements to cooperative software agents: comprehensibility, accessibility, joint attention, and intermittent participation. Accessibility means that the action potentials and desires of one participant should be accessible to the others. We can do this by letting the interface show which actions are possible in the current habitat (as already illustrated in Figure 5 and Figure 9) and what the fictive effect of the action is. For example, when a child is near a fictive or real sausage, the display shows that the action of taking the sausage is possible and that it may lead to enrolling dogs in the child’s team. Similarly, when a child approaches a fictive dog, the display suggests that it is now possible to give the sausage to the dog.

If a player wants to know more about a non-player character’s (NPC’s) attitude before interacting with it, he or she may take a closer look first (by using the scan mode described next).
The game is designed in levels of increasing complexity. In the beginning, you only have to find candy. No bogeyman. Then come the mice (an Antagonist) and begin eating your candy. Then cats, which are useful because they eat mice. Then, at last, the dogs and the bogeyman. Dogs protect you from him, but if there is a cat nearby, they may run after the cat instead. If you forget to feed them, they may get angry and bite you. The mice will come out of the sewers, which are connected underground.

When players meet, they can fight each other, but they don’t have to do it. Strength is measured by the amount of candy they have. They can freely negotiate offline, if they prefer (e.g., that the weaker player gives some candy to the stronger team) (security payment). They also can have a virtual fight throwing different objects and power-ups at each other. If they fight and one of them loses, the winner takes all the loser’s belongings. If you find other players’ home bases, you can strip them of all their belongings. A base is defined by a Bluetooth tag. You probably have to look around a bit in order to see it. When you reveal their base, their icon explodes, and they must come to you and collect it to set up a new base. They do this by placing their tag somewhere else.

According to (11) in section “Activities,” execution of actions changes the glue binding

---

**Figure 10. Dependencies between actions in Bogeyman**

![Diagram of dependencies between actions in Bogeyman](image-url)
participants to other actions, and so changes of these dependencies must be an integrated and visible part of the game. Figure 10 shows the dependencies between the actions. As in section “Activities,” we abstract the participant-glue-role relations into three main relations: possibility, necessity, and impossibility in order to maintain overview. To give an example, the capture of the children by the bogeyman is prevented by him running away, which is triggered by dogs chasing him or by the children running away. The capture also can be prevented by the dogs catching the bogeyman. A capture will prevent children from taking more candy; but, and this is the snag, collecting candy is the one action that makes it possible for the bogeyman to catch the children. Collecting candy is risky.

As appears from the +/- marks, dogs desire to catch cats and eat sausage, cats to eat mice and fish, children to eat candy, mice to eat candy and to multiply, and bogeymen to catch children. On the other hand, mice hate being eaten by cats, bogeymen to be caught by dogs, and children to be caught by bogeymen. Thus, the diagram contains conflicts that can be used in a narrative: mice oppose being eaten but cats think it is a good idea; bogeymen like catching children, but children are dead against it. There are also implicit conflicts: mice eating candy prevents children from doing it, and vice versa.

A cursory inspection of the diagram shows that it also contains explicit and implicit contradictions: the children’s taking candy enables the bogeyman to catch them, which again prevents their taking it; the children’s giving sausage to dogs prevents dogs from chasing cats (which they desire) but enables them to eat sausage (which they also desire). Mice entering the sewers prevents them from eating candy (which they love to do) but saves them from being eaten by cats (which they don’t like). The contradictions and conflicts are built into the rules in order for them to generate an interesting narrative, but a consequence is that we cannot use standard logic to implement the rules.

Two rules used by the system are not shown in the diagram, because they would clutter it completely: cats eat mice obstructs all actions in which mice participate: mice multiply, mice enter sewer, mice leave sewer, and mice eat candy. Similarly, Bogeyman catches children obstructs all actions involving children: children give sausage to dogs, children give fish to cats, children take candy, children take sausages, children take fish, children run away, and children eat candy.

Note that we have only distributed desires to a few actions: as it stands, dogs only know that they like to catch cats and eat sausage; they have no particular desire to chase and catch bogeymen or to chase cats. In addition, they have no attitude toward bogeymen catching or not catching children. The idea is that such derivative attitudes should be generated as an emergent phenomenon as the game progresses. Enrolling virtual agents as helpers and avoiding defections to the enemy should be part of the gameplay. Thus, Figure 10 only works as a seed for the game.

The second desideratum was a better interplay between the real and fictive habitats. We shall deal with that now.

The phone is the primary artefact in the informational habitat. It has three modes that are

related to the physical habitat: proximity, global, and scan (Table 2).

In the proximity mode, the player can see all objects of the real and fictive habitat within the field of vision. In the global view, the player can only see other players and the map of the arena, including the player’s own home base. The scan view offers a closer look at something (e.g., the attitude of an animal or the presence of a fictive sausage), but it also obstructs the other two views. Whenever a player is in the scan view, it is reflected by the player’s representation in the global and proximity view. This is useful information to other players because they now know that there may be something interesting to check out at that location. Players can also allow each other actually to share their proximity or scan view, thus enhancing each other’s access to information.

Figure 11 shows the three informational modes of a habitat. The scan and proximity modes are relative references that change as the player moves. The global mode is an absolute reference (dashed arrows), since the whole playing area is accessible all the time. The scan mode differs from the two other in that the access area is defined by the location of the reference and not by the receiver. The reason is that the referent (the NPC in Figure 11) carries a Bluetooth tag that creates an information cloud (access area) around it with information about it. If the mobile phone in Figure 11 is Bluetooth-enabled, it can receive this information.

The mobile phone in Figure 11 always can see the global layout of the game area; it can see more details in the local area around it; and it can scan the NPC since the phone is inside the access area of the NPC.

Figure 11, however, does not capture the interplay between the actual and the fictive in the game. In order to do that, we need the concept of fictive habitats introduced in section “Habitats.” Parts of the game exist in the real physical habitat; this is true of the sewers and the children and possibly of the candy and sausages, depending on how you set up the game—and possibly a child may wish to play the bogeyman. Some of the actions also exist in the real habitat; for example, the action of walking and running. However, the game rules only exist in the fictive habitat, and all the participants in the game must have a fictive representation as well. Otherwise their actions could not influence the game state.

Of course, we can depict this dichotomy as in Figure 9 by drawing the actual and the fictive habitat side by side. But here, the correspondence between the fictive and the actual positions of the participants does not stand out. In the following, we collapse the two diagrams into one. The fic-

Figure 12. Basic setup with two players, the bogeyman, some candy, and the home bases

![Diagram of basic setup with two players, the bogeyman, some candy, and the home bases.]

Figure 13. Space-time plot of discrepancies between the physical and fictive habitat

![Space-time plot illustrating the effect of delaying dog shit (topmost) and the effect of a shadow on autopilot (bottommost).]

tive diagram is the main one, since it defines the game state. If a fictive participant has a real-world counterpart, we show this by adding a shadow to the fictive entity. Thus, the real world is shown as a platonic projection of the fictive world. We distinguish between fictive (only in the fictive habitat), real (only in the real habitat), and mixed entities (both in the fictive and real habitat).

Figure 12 shows the basic setup with two mixed players (C), a mixed bogeyman (B), three pieces on fictive candy (S), one piece of mixed candy (S), two fictive mice (M), and one fictive dog (D).

In addition to candy and sausages, there are a number of special items, power-ups, the players can encounter: a dog shit, a shadow, and a torch.

The shit is left by dogs, and if you run over it, you slip, and your avatar is slowed down. You have to slow down yourself, because generally, if you are not close to your avatar, it shifts to autopilot and begins moving on its own. Holiday!

If you walk carefully past the shit and do not tread in it, you can pick it up and drop it later at your convenience (e.g., in front of another player). The stickiness is, of course, entirely virtual and only causes the virtual representation of the player to move slowly.

The shadow, inspired by H. C. Andersen’s fairy tale, The Shadow, is a way to disguise the actual location of a player. When it is activated, the player’s avatar will use dead reckoning to move in the same direction, regardless of the actual movement of the player. In this way, a player can sneak up on another without being noticed. The problem is that if your avatar meets any other avatar, it gets scared because its master is not present, it flees in an erratic manner, and the child must catch it.

The space-time plot in Figure 13 illustrates the effect of delaying dog shit (topmost) and the effect of a shadow on autopilot (bottommost).

The torch (Figure 14) is a way of showing a virtual or mixed entity A to another virtual or mixed entity B. The torch can be implemented as a highlight or a cursor. In Figure 14, an arrow is used. The arrow belongs to the fictive world and, therefore, exists in the fictive reference area on a level with fictive mice and dogs. Each user can manipulate his or her torch. Since the torch is a pointing device, it should only be visible in the proximity mode—you only point out things to people close to you, and physical proximity serves to delimit the number of addressees.

The torch is thus a way of establishing the shared focus of attention between participants, as required in section “Activities.” From the perspective of semantic roles, the torch is a way for...
an agent (C) to increase the glue between another agent (B) and a role in an activity that involves the entity in focus (A). If a child points to a sausage in the presence of a dog, it strengthens the desire of the dog to play the role of Agent in the affordance of the sausage (namely, that of being eaten by a dog).

The torch can also be used to move the focus of the dog away from the affordance of cats (being chased) to the affordances of sausages (being eaten) or bogeymen (being chased away). A mean way of using this technique is to reveal the other players to the bogeyman and make him hunt them.

The game ends after a fixed time or whenever it is suspended by the players. Players can enter and leave intermittently.

In section “Starcatcher,” we decided that the ability to participate in activities is created by spatial movement: if the participants are assembled in the same place, they are able to participate in the activity. But, as mentioned in “Activities,” the activity will not execute unless the Agent participant desires or is obligated to do it. How do we provide these desires?

**Designing Intelligent Agents**

In this section, we will discuss how to implement the distribution of desires mentioned in the previous section. Mice and children are clearly competitors: how can we make the mice aware of this and possibly begin oppose the children (e.g., by supporting the bogeyman in catching them)? How should the cats react toward chasing mice: on the one hand, chasing them leads to the desired action of eating them, but it also enables the mice to flee to the sewers, which disables the eating. We would also like to generate attitudes between participants: who sides with whom? Will the mice oppose the cats and side with the children (although they compete for the candy)? Will the dogs assume the role of helpers to the children, even if helping out prevents them from chasing cats? In short, will global narrative roles emerge from the interplay between the actions?

Which methods should we use to make this come about? We realize already that since the story contains contradictions, we cannot use standard logic for these inferences. Classical AI is thus not an option. In order to choose a solution, let us first look at our requirement lists, repeated as follows for convenience:

1. Intelligent technology is a kind of technology that is able to contribute positively to activities whose manner of performance we will intuitively call intelligent.
2. Agents should have intentions to act that are understandable to the others (comprehensibility).
3. Agents should be able to enter and leave the activity (intermittent participation).
4. An activity is executed if all participants are able to fulfill their roles to some degree and the Agent filler is strongly obligated and/or strongly desires to fulfill his or her role.

(1) says that the algorithm must refer to networks of actors, not to the individual actor; (6) says that the rules it uses must be known to the human users.

One interesting possibility is the theory of cognitive dissonance (Eskola, 1973). The theory allows us to calculate the relation z between persons A and C, if we know the relation x between A and B and the relation y between B and C. It (regrettably) works well for international politics, so we take the fight against terrorism as an example: if
George W. Bush (A) opposes (x) Al-Qaeda (B) and Al-Qaeda supports (y) the Taleban (C), then George (A) opposes (z) the Taleban (C) (Figure 15). In some cases, it is also possible to calculate z if we know x and the inverse of y, y'. If George opposes Al-Qaeda and Taleban promotes Al-Qaeda, then George opposes the Taleban (Figure 16).

If the Danish Prime Minister Anders Fogh supports George Bush, and Bush supports the policy of waging war against Iraq, then Fogh, too, supports waging war against Iraq. We can use the last observation for action selection, as required by (10): when Fogh supports waging war against Iraq, this means that he desires to assume the Agent role in war activities (which, in fact, he did).

The rules can be made to cover normal means-end planning: if occupying Iraq (means) promotes (y') a stable and profitable supply of oil (end), which George very supports (x), then George promotes occupation of Iraq (z). Or, if occupation of Iraq, which George supports (x), necessitates (y) that the American arms budget is increased, then George must support the increase, too (z).

We can, in fact, also leave persons out of the equation: if the occupation of Iraq promotes (x) a democratic government in the country, and democratic government in Iraq promotes (y) a more peaceful world, then the occupation (indirectly) promotes a more peaceful world.

In all of these very real examples, the following two simple rules have been used (≡ is logical equivalence):

18. \( z_t = (x_{t-1} \equiv y_{t-1}) \)

19. \( z_t = (x_{t-1} \equiv y'_{t-1}) \)

\( Z \) at time \( t \) is calculated as the equivalence of the \( x \) and \( y \) (or \( y' \)) relations at time \( t-1 \). At the same time, the rules provide explanations for the attitudes: \( z \) holds because \( x \) and \( y \) hold. George opposes the Taleban because they promote Al-Qaeda, and he opposes Al-Qaeda.

There is one problem, however. As we have already seen, we cannot assume that such networks of actors and actions are consistent in good narratives. Therefore, we often will encounter the phenomenon that the same relation will be calculated differently if we use two different triangles that share one side. This is the problem of overwriting. George Bush endorses an occupation that leads to casualties; therefore, George ought to be in favor of the casualties (rightmost triangle in Figure 17). However, he also likes his voters, who are opposed to casualties. Therefore, George ought to be opposed to casualties (leftmost triangle). If the leftmost triangle in Figure 17 wins, George may change his attitude to the occupation in order to avoid dissonance (e.g., begin opposing it). If the rightmost triangle wins, he has to support casualties (which is the strategy of his op-
ponent: the young suicide bombers are celebrated as martyrs). Machines do everything in a fixed order, so if the rightmost triangle is processed last, it always will overwrite the influence from the left triangle. In order to allow George Bush to change his mind with respect to the casualties, we introduce a random factor in the application of the rules. Sometimes one triangle is chosen, sometimes the other, and sometimes both. This has two advantages: (1) all the triangles are allowed to have an effect, and (2) the “thinking” of the software agents is not momentary but proceeds piecemeal, sometimes overlooking logical inferences in the first round.

However, endorsing the casualties is really no option at all for George for deeper ethical reasons than voter-tactical considerations. There are basic ethical attitudes that are stronger than others and should not easily be changed. In Western cultures, the respect for human life is (officially) very high and cannot easily be changed (publicly). Instead, contradictions should be allowed to remain in some cases. We therefore introduce a measure of strength of the attitudes: weak, medium, and strong.

We also make a distinction between relations where the first A-term is a person and those where it is an action. A person can have subjective desires that can be changed, but actions do not desire anything. They can enable or cause another action.

In summary, we make four modifications to the original simple calculations.

20. Relations between actions only are allowed to change from an unknown 0-state.
21. Relations between persons and between persons and actions can change if they are not strong.
22. The strength of the feelings of a person toward an action propagates to the actions or persons that enable or oppose the action.
23. Rules are applied with a probability between 100% and 0%.

We distinguish thus between immutable factual relations between actions, and mutable subjective attitudes toward actions.

The reason for (22) is the following: if mice strongly dislike to be eaten and being caught by cats enables the eating, then mice should strongly dislike being caught. Cats look quite differently upon the subject: if they strongly like to eat mice and catching them enables this, then cats should be strongly in favor of catching mice.

(20–22) give the network a certain degree of stability, because they restrict the possible changes.

The following algorithm uses three simple data structures. **Network** is a list of actors and their type, `<actor or action, type>`, where type can be P = participant and A = action. **Relation** is a two-dimensional list representing the relation between actors and actions: Relation[i,j] means the relation from i to j. The relation can be “+”, i supports j, “0”, they are indifferent, or “-“, i obstructs j.

Finally, **Strength** is another two-dimensional list where Strength[i,j] represents the strength of the relation from i to j. The strength can be “++”, strong, “0” medium, and “-“ weak.

The rules for overwriting are as follows: a non-zero relation can be overwritten if and only if the source of the relation (the Atype below) is an actor and the relation is not strong. If George

![Figure 17. Contradiction of attitudes](image)
has very strong ethical feelings against casualties in Figure 17, then the rightmost triangle cannot overwrite it.

The different triangles are classified according to the type of their endpoints: thus, PAA is a type where an actor, type P, has a relation to an event, type A, that has a relation to another event, type A.

It is not possible to evaluate the usefulness of the individual triangle in isolation. The PAA case corresponds to the proverb, “If you have said A, you must say B as well.” It is not included in the following algorithm, but it was in the beginning, since it sounded at least as sensible as PPP, “my friend’s friend is my friend.” In both cases, there are exceptions. An example is George Bush’s dilemma where A = George, B = occupation, C = casualties. Bush can evade the responsibility for the casualties by claiming that they are an unfortunate and unintended consequence of an otherwise good deed. In the PPP case, one can argue that the friend made a mistake in cultivating a disrespected person and, thus, not extend one’s own friendship to this person.

PAA was deleted from the algorithm, not because of its inherent qualities but because its effect in the global network was detrimental, as we shall see next.

The algorithm is as follows, written in pseudo-code:

```plaintext
RemoveDissonance (network, relations, strength)
repeat for all elements a of the network
  record the type of element a in Atype
  if Atype = "P" and Chance() then
    -- agents like themselves.
    set the relation of a to itself to +
  end
repeat for all elements b of the network
  record the type of element b in Btype
  record the a/b relation in x
  if Atype = "P" and Btype = "P" and the strength of b/a ≠ + and Chance() then
    --- if you like me, I like you.
    set the relation b/a to the relation a/b
  end if
  if x ≠ "0" then
    repeat for all elements c of the network
      if a = c or the strength of a/c = + then next
      repeat
        --- strong relations cannot be changed!!
        record the type of element c in Ctype
        record Atype+Btype+Ctype in theCase
        record relation b/c in y
        record relation c/b in y'
        record relation a/c in z
        if y ≠ 0 and chance() then
          choose between two cases
          case (thecase = "PPP" or thecase = "PPA")
            --- relations where a is an agent
            set relation a/c to equiv(x, y)
            set the strength of z to the strength of x
          end if
          case (thecase = "AAP" or thecase = "AAA")
            --- relations where a is an action
            set relation a/c to equiv(x, y)
          end if
        end if
        if y' ≠ 0 and chance() then
          --- here we know the inverse of y
          if (thecase = "PAP" or thecase = "PPA" or thecase = "PPP" or thecase = "PAA")
            --- relations where a is an agent
            then
              set the relation a/c to equiv(x, y')
              set the strength of z to the strength of x
            end if
          end if
        end if
      end repeat
  end if
end repeat
end RemoveDissonance
```
The algorithm moves the network of attitudes toward a consonant type by removing dissonances. If a consonant version exists, it will arrive to it through a number of iterations.

George’s dilemma can run as follows (with the PAA possibility included): the seed is Figure 18: George promotes his voters and strongly promotes the occupation, the voters are against causalities, and occupation promotes causalities. After three iterations with a rule probability of 50%, the situation is as shown in Figure 19: George still strongly promotes the occupation and, in addition, the casualties, while he obstructs the voters. The voters retaliate and strongly obstruct George as well as the occupation and causalities. At this time, George’s attitudes were changed in the simulation so that he now strongly promotes his voters. After a few iterations, this changes the whole picture to Figure 20: now George strongly obstructs occupation and casualties but has gained the love of his voters.

Thus, change of action potentials is created by a single change of attitude that ripples through the network in a change of cause and effects.

If we run the dissonance algorithm on the StarCatcher, we will see two teams opposing one another and opposing everything the other team does. There are no surprises, and this agrees with the fact that StarCatcher is a simple zero-sum game. Things are quite different in Bogeyman, since it contains conflicts and contradictions. The participants have their own agenda and create alliances to further their own interests. Bogeyman requires strategic thinking of the children.

In the following, we make some comments on initial experiments that use Figure 10 as seed. The algorithm is being elaborated and refined at the moment.

Figure 21 shows the attitudes developed after four iterations.

Two main groups seem to be forming: cats, dogs and children on one side; bogeyman and mice on the other side. However, there are still some conflicts: cats and mice like the bogeyman but are opposed by him.

The simulation recorded a log of the attitude changes, and this log can be used as explanations for the attitudes. As the following examples show, these explanations seem quite understandable:

- *Cats promote children* because both oppose mice. Cats oppose mice because cats want to eat mice, which mice don’t like. Children, on their side, oppose mice, because the children want to take candy, which the mice don’t want them to for the obvious reason that then it is gone when the mice come to eat.
The Semiotics of Smart Appliances and Pervasive Computing

Figure 21. Bogeyman after four iterations

- **Cats promote the bogeyman** because they both oppose mice eating candy. The cats’ reason for this is that they are enemies of the mice, who like eating candy—cats are against actions their enemies like to do. The bogeyman, on the other hand, doesn’t want the mice to take candy, because it hinders him in catching the children—it is the children’s picking up candy that enables the bogeyman to catch them.

- **Dogs oppose the bogeyman** because they don’t want him to catch children, which he likes. The reason for the dogs’ opposition is that they like to eat sausage, and this is prevented if the bogeyman catches the children: if they are caught they cannot feed the dogs.

- **Dogs promote children** because neither of them wants the bogeyman to catch children. The reason for the dogs’ opposition to child capture is that dogs like to eat sausage, which is obstructed by the bogeyman catching the children.

- **Dogs promote mice** because both want the dogs to catch cats. The mice’s reason is very sensibly that dogs catching cats prevents cats from catching mice.

- **Mice oppose children** because children want cats to eat mice, which the mice naturally don’t like. Children, on their part, want cats to eat mice because children want candy, and cats eating mice supports their candy hunt since it puts a stop to mice eating the candy, which prevents the children from getting hold of it.

- **The bogeyman opposes dogs** because he doesn’t want the children to give sausage to them, but the dogs like very much to be fed. The reason why the bogeyman opposes this sausage distribution is that it causes the bogeyman to run away, which he does not want, since running away prevents him from catching the children, which is his goal in life.

- **The bogeyman opposes mice** because he wants children to take candy, and mice hinder this. The bogeyman wants children to take candy, because it enables him to catch them, which he very much wants.

After the four iterations, most agents thus have developed understandable attitudes toward most actions and agents. However, a few of them turned out to be somewhat strange. Here is an example: it turned out that cats want dogs to catch them (!) because they did not want mice to enter sewers. Dogs catching cats prevents this. The reason why cats don’t want mice to enter the sewer is that they want to catch the mice, and this is not possible when the mice are in the sewer. The reason for the error lies in the seed: we forgot to add that cats strongly oppose being caught by dogs.

In earlier versions in which the PAA type was allowed, we got really weird explanations; for example, the bogeyman opposed children giving fish to cats because he wanted to catch children, and this prevented the children from giving fish to cats. The triangle type is PAA that lets a person transfer his or her attitude from an event to its effect, which seems pretty unintelligible in our case; there is no reason why the bogeyman should oppose children giving fish to cats, even if he indirectly prevents it by catching the children.
Evaluation of the Algorithm

The small experiment shows the following:

24. The dissonance algorithm does produce understandable attitude changes and divides the participants into groups that support or help one another.
25. The explanations given for the attitude changes are understandable.
26. The value of the individual rules must be evaluated through their global effects on the network through experiments. It was not possible to predict that the PAA triangle in itself would be detrimental.

Let us review our requirement list from the previous sections to see how the algorithm fares:

1. Does it produce technology that is able to contribute positively to networks of activities whose manner of performance we will intuitively call intelligent? The “intelligence” of the software agents is clearly a network phenomenon since attitudes develop in the context of other agents’ attitudes.
6. Agents should have intentions to act that are understandable to the others (comprehensibility). The results show that the attitude changes are understandable and that the agents can provide reasonable explanations.
9. Agents should be able to enter and leave the activity (intermittent participation). Since the algorithm recursively tries to remove dissonance in the network, addition or deletion of agents will not spoil anything but possibly may make the network move toward other equilibrium states.
10. Does it conform to the rule that an activity is executed if all participants are able to fulfill their roles to some degree and the Agent filler is strongly obligated and/or strongly desires to fulfill his or her role. The algorithm works by distributing desires of the agents toward actions and other agents. It thus produces one of the glue-components that causes agents to act. The other, ability, is produced by physical movements.

A drawback of the method is that the effects of changes to the seed and the algorithm are difficult to predict, but this is the price you pay for designing emergent games. The designer to some degree loses control over the product.

Another problem could be that the software agents are too intellectual in the sense that their motivations are caused by reasoning with many steps, which children may not be able to follow. On the other hand, many adventure games have plots that are more complicated.

Evaluation of the Framework

Did the framework give us good ideas as we hoped? It turned out it was very productive in generating ideas for playing with physical vs. fictive reality. It was also very good at associating activities to space and participants to activities in a simple coherent way. Bogeyman took about an hour to invent. In addition, the framework maintained a foothold in the computational world and gave indications of possible technological solutions. It worked as a boundary object connecting the aesthetic and the technical world.

The small simulation showed a possible way of combining games of emergence and narrative games of progression, a combination that was judged impossible in Juul (2005).

Because of its robustness, it is very easy to add or delete participants from the game, which makes us hope that it can be developed into a toolkit for the children themselves to modify or build games.

The diagramming techniques clearly need to be developed further. Small games are easy to specify, but more complicated games need conventions for abstraction and decomposition.
also should be emphasized that we lack empirical evidence that the games specified in this way are actually fun to play!

**Future Developments**

The simulation does not deal with the balance between reasoning about actions and executing them, although the conditions for executing actions are well-defined (see (10) in the section “Activities”).

The next step, therefore, is to orchestrate the percolation of desires in the network and the execution of these desires. One convention could be that an action is not allowed to influence other actions before it is executed; only when an action is realized may it have effect on other actions. An even stronger restriction is that only participants who have experienced the execution of the action are allowed to change their attitudes because of it. In this way, the network changes would be much easier to follow, and both solutions will reduce the part of the network that the algorithm must search and thereby decrease the complexity of the algorithm, which regrettably is \( \Theta(n^3) \).

However, the two conventions are probably too strong. On the one hand, communication probably should count as a kind of execution: when the Bogeyman tells the mice that he doesn’t like them to eat the candy, this should make the mice reconsider their positive attitudes toward the bogeyman with the same force as if he had actually prevented them from eating candy. Similarly, a promise from the children to give sausage to dogs should make the dogs side with the children as if they had actually given sausages to the dogs. On the other hand, some degree of secret reasoning is a good literary trick—it invites the reader/player to reconstruct the possible reasons for unexpected behavior.

But the whole play is, after all, staged for the benefit of the children. In order for them to create their tactics, it seems a good idea to inform the children of the interactions between the software agents so that they can understand what is going on and make their plans accordingly. Literature and films have the same problem: how do we inform the reader/viewer of several concurrent happenings when we can only tell about one event at a time? The solution is to let the characters meet, tell stories about their adventures, and let the reader/viewer overhear the storytelling. Should we do a similar thing in the game so that when the children meet a dog, it will tell them about the feeling and atmosphere in the canine world?

But then again, maybe the children should be required to seek the information themselves, at least at advanced levels. The ultimate criterion for deciding is still: is it fun?

**RELATED WORK**

In this concluding section, we compare our approach to a number of related approaches in which notions like communicative acts, activity, semantic roles, context, and pervasive games are central:

- **The Language Action Perspective (LAP) Community**: This community is inspired by the works of John Searle and Jürgen Habermas on communicative actions. The approach to artifact design in Winograd & Flores (1986) also has been an inspiration to the community. LAP basically views use of IT as the execution of speech acts mediated by technology. The notion of speech acts is also central to this chapter, but we extend the concepts to also cover noncommunicative material acts and the relation between the two. The LAP community has emphasized the communicative type but to a certain degree has failed to realize that communicative actions are intertwined with material acts in actual work processes. There is, therefore, a need to build an integrated theory that encompasses the two (Goldkuhl,
The bias toward communicative actions, for example, can be seen in the DEMO method described in Dietz (2003). It offers a finely grained typology of communicative acts (request, promise, decline, quit, state, accept) but only distinguishes between two material acts (deliver, sell). Another problematic feature, which is also noticeable in DEMO, stems from Winograd & Flores (1986): conversation patterns are primarily described in temporal terms: one act comes before or after another act, like in a finite state automaton. The problem is that mere temporal sequence does not explain the reason for the communicative pattern, and it is difficult to relate to organizational issues. The notion of glue in this chapter offers a more detailed method of description: actions hang together because one action changes the abilities, rights, and obligations of an actor to participate in other activities. Since qualifications and norms are central to organizational analysis (Liu, 2000), our framework seems easier to relate to organization theory.

**Activity theory**: Activity theory originated from the dialectical materialist psychology developed by Vygotsky and his students in the Soviet Union in the beginning of the 20th century. Activity theory goes beyond the popular human-machine dyad and insists on cultural and technical mediation of human activity. Therefore, the unit of analysis includes technical artefacts and cultural organization, and the focus of activity theory is much wider than what has been the core concern of past HCI research (Bødker & Andersen, 2005). But activity theory seems to have the opposite problem of the LAP community: it emphasizes material activities in which a subject applies a tool to change some object, and only recently has spoken and written discourse begun to figure as mediators in activity theoretical analyses of work, and the effort to explore their role as mediators has been limited (Wells, 2002). The chapter has borrowed the notion of activity from activity theory but has extended its three basic concepts—subject (agent), mediator (instrument), and object (theme)—by means of the theory of semantic roles.

**Actor-network theory (ANT)**: ANT is not a real theory but rather a number of related methodologies and assumptions (Latour, 1999; Law, 1987) focused on empirical ethnographic fieldwork. This chapter obviously is inspired by this tradition with its emphasis on the significance of networks and its (structuralistic) insistence that participants in the network primarily acquire their properties from their position in the network and not from inherent resources. We deviate from the tradition by insisting that it is possible to refine the vague concept of actor into a set of more precisely defined roles in a network. The roles we have chosen are borrowed from the theory of semantic roles, and the reason why we believe these roles to be real is that they have been formalized in natural languages over many thousands of years by means of prepositions and case inflexions. We thus view the roles as the result of an evolutionary process in which practical experience through the millennia has distilled relevant distinctions. Another deviation is that our framework is biased toward design of pervasive technology, which is not the case with ANT.

**Object-role management (ORM)**: ORM (Halpin, 1998) is an alternative to traditional entity-relation modeling and object-oriented modeling. "ORM is a method for designing and querying database models at the conceptual level, where the application is described in terms readily understood by users, rather than being recast in terms of implementation data structures" (Halpin,
An ORM model consists of a set of objects that play roles similar to actions in Digital Habitats. In our understanding of ORM, it resembles a slot-and-filler grammar similar to ours and to Fillmore’s “Frame Semantics” (Schalley, 2004).

ORM focuses on databases, design, and querying, and it has strong formal properties (e.g., formalized conversion to ER/OO/SQL and nesting). It makes clear distinctions between issues that belong to the conceptual level (how the users understand the problem domain) and those that concern the implementation (e.g., the OO concept of inheritance tends to become very abstract from the problem domain perspective). Thus, ORM is well-suited to validate a model together with domain experts that know nothing or little about programming, because the ORM model can be populated with sample data in a way that reflects the domain on the conceptual level. ORM is supposedly superior to OO when it comes to transformations over time, since it does not use attributes (although facts can be collapsed into attributes for easy overview), which allows for model changes without major restructuring. On the other hand, it only handles the static properties of a model, according to Halpin (1996, 66), since it is the most stable part of the model (although various ORM extensions have been proposed for process and event modeling).

Compared to ORM, Digital Habitats is well-suited to the handling of dynamic models, and ORM lacks the integration of physical and, to a large extent, pragmatic aspects. However, ORM is simpler and has a more formal and consistent design than Digital Habitats.

**Unified eventity representation (UER):**

UER (Schalley, 2004) is a quite recent, UML-based attempt to develop a representational framework for verbal semantics [i.e., verbs, not speech] that is formal and intuitive at the same time. This means in effect proposing a framework that is in principle computer processable on the one hand, and yet on the other hand whose representations reflect the wealth and flexibility of natural language in an intuitively plausible way and in accordance with our current knowledge about natural language. (Schalley, 2004, p. 1)

Based on Unified Modeling Language (UML), it combines computation-oriented diagrams with a solid linguistic approach to compositional semantics. It proposes a diagram-based framework that is precise and yet potentially underspecified. In the context of analysis and design of pervasive games, it seems too fine-grained; however, much insight can be gained from the analyses and discussions that are presented in Schalley’s (2004) proposal.

**Context-awareness:** Context-aware systems stand out as a fairly distinct field within computer science. The Context Toolkit (Dey, Salber, & Abowd, 2001) differs from Digital Habitats in its technocentric orientation. It is a set of concepts that provides concepts and standards for things primarily at a technical level. There is a set of higher-level concepts, but these are developed on top of the technical concepts rather than the other way around.

**Pervasive gaming theory:** Walther (2005) offers a set of concepts to classify and analyze pervasive games. They target important distinctions and issues, and they may well be used in a generative manner, but compared to Digital Habitats, they are much more general in nature and do not support detailed analysis and design.
CONCLUSION

Based on the comparisons in the previous section, we can identify six areas in which the present approach seems to present advantages:

- It provides a description of action dependencies that is not a mere temporal sequence but is relatable to organizational concepts like qualifications and norms (as compared to the LAP tradition).
- It provides a better framework for describing communicative as well as material acts plus the way they hang together (as compared to the LAP tradition and activity theory).
- It provides an explicit link between human activities and their spatial context (as compared to the technical literature on context-awareness).
- It has an explicit dynamic model that precisely describes the conditions for executing actions (as compared to the ORM methodology).
- It offers a typology of participant roles, based on linguistic evidence that reduces complexity and, therefore, supports design processes (as compared to Actor Network Theory and pervasive gaming theory).
- By using semantic roles, it encourages a system architecture that is verbalizable (i.e., which automatically or semi-automatically can produce understandable descriptions of themselves) (Andersen, 2004b).
- Technological artifacts are described according to their function in activities (Bødker & Andersen, 2005). Some automatic systems function as Agents since they initiate and control the activity, others function as Instruments that do not do anything by themselves, while still others function as Beneficiaries in which other participants perform activities on their behalf.

ACKNOWLEDGMENT

The authors wish to thank the anonymous reviewers for their detailed critical remarks and good suggestions. Part of this work has been supported by Center for Interactive Spaces, ISIS Katrinebjerg (Project #122). Thanks to our colleagues in the research group Frameworks for Understanding Software-Based Systems, which has been a great inspiration for this chapter.

Chapter 2.13
Analyzing the Factors Influencing the Successful Design and Uptake of Interactive Systems to Support Social Networks in Urban Neighborhoods

Marcus Foth
Queensland University of Technology, Australia

ABSTRACT

In urban residential environments in Australia and other developed countries, Internet access is on the verge of becoming a ubiquitous utility like gas or electricity. From an urban sociology and community informatics perspective, this article discusses new emerging social formations of urban residents that are based on networked individualism and the potential of Internet-based systems to support them. It proposes that one of the main reasons for the disappearance or nonexistence of urban residential communities is a lack of appropriate opportunities and instruments to encourage and support local interaction in urban neighborhoods. The article challenges the view that a mere reappropriation of applications used to support dispersed virtual communities is adequate to meet the place and proximity-based design requirements that community networks in urban neighborhoods pose. It argues that the key factors influencing the successful design and uptake of interactive systems to support social networks in urban neighborhoods include the swarming social behavior of urban dwellers; the dynamics of their existing communicative ecology; and the serendipitous, voluntary, and place-based quality of interaction between residents on the basis of choice, like-mindedness, mutual interest and support needs. Drawing on an analysis of these factors, the conceptual design framework of a prototype system — the urban tribe incubator — is presented.
INTRODUCTION

The area of technology and human interaction is cross-disciplinary and requires many different academic fields and design practices to work together effectively in order to generate a better understanding of the social context and human factors in technology design, development, and usage. This article focuses on the social communication aspects of this field and hopes to establish a greater awareness of the contribution that community media and communication studies can deliver to the field of human computer interaction. It seeks to build a theoretical foundation for an analysis of two interrelated issues, which are discussed in turn.

First, the importance of place and the continued purpose and relevance of urban neighborhoods are established. New media and networked information and communication technologies have not led to the diminishment of local place and proximity. However, they have given rise to new types of social interaction and to new emerging social formations. Understanding the nature and quality of interaction in these new social formations can inform the successful animation of neighborhood community and sociability.

Second, appropriate opportunities and instruments to encourage and support local interaction in urban neighborhood networks are not limited to technology, but technology can be a key facilitator. Thus, system designers and engineers are crucial allies to social scientists in the search for hybrid methodologies that integrate community development approaches with technology design. The article questions whether it is sufficient to appropriate tools originally designed for dispersed online (that is, virtual) communities in the context of community networks (Schuler, 1996) for urban neighborhoods. Purpose-built tools and instruments are required that afford

(a) interactive linkages between the resident’s communicative ecologies of cyberspace and local place; and
(b) personalized social networking between proximate neighbors of choice. Such an approach would allow the nonvirtual and place-based assets in a resident’s portfolio of sociability to become more attractive. It would establish an opportunity to create and to maintain local social ties and, ultimately, to find out who is living next door and who is personally compatible.

From the discussion of these issues, some of the key factors influencing the successful design and uptake of interactive systems to support social networks in urban neighborhoods are derived. Drawing on an analysis of these factors, the conceptual framework of a prototype system — the urban tribe incubator — is presented.

This article seeks to set up the interdisciplinary conceptual foundation necessary to drive a thorough theoretical and empirical investigation into the interaction of people, place, and technology and the way they function together to facilitate access to the social and cultural life of cities. The purpose of this article is not only to introduce and illustrate the issues at stake and to present a design framework but also to stimulate transfer and exchange of knowledge across academic disciplines and especially to invite discussion and comment from a broader interdisciplinary audience. Supporting efforts to build bridges between the social and engineering sciences is paramount to the field of technology and human interaction, and this article contributes to the development of a dialogue between these disciplines. An interdisciplinary approach that brings together views and expertise from sociology, urban studies, interaction design, and related disciplines will assist with efforts to facilitate urban neighborhood community building, social inclusion, public consultation and debate, fair access to local information and services, urban sustainability, and healthier local economies.
The Internet has found its way into many households of urban dwellers in Australia and other developed countries to the extent that Internet access is on the verge of becoming a ubiquitous utility like gas and electricity. The Internet has advanced to become a communication tool that coexists with other established communication devices such as the telephone, short message service (SMS), new media, and face-to-face interaction. E-mail, instant messaging, online chats, and other online applications are now instrumental in establishing and maintaining social ties with family, friends, coworkers, and other peers, thus creating a private “portfolio of sociability” (Castells, 2001, p. 132).

The Internet has entered people’s everyday life and plays a significant role in the communication pattern of urban residents. The Internet has not substituted but supplemented off-line interaction with online interaction (Fallows, 2004; Wellman & Haythornthwaite, 2002). People still chat on the phone and meet face-to-face. However, the Internet as well as mobile communication devices such as mobile phones, laptops, and personal digital assistants (PDA) allow people to maintain social ties in different ways by taking advantage of new features. The mobile phone introduced place-independent communication, and the emerging third- and fourth-generation (3G, 4G) mobile telephony adds audiovisual telepresence. E-mail and SMS afford asynchronous communication and notification mechanisms. Online chats offer broadcast-style, many-to-many communication, whereas private chat rooms enable users to engage in multiple peer-to-peer dialogues. Instant messaging tools combine the features of online chat rooms with ambient awareness by adding availability or other status information to a user’s nickname (e.g., Jean|busy, Lucy|out to lunch).

However, these tools are used more often to connect with family, friends, coworkers, and peers and less with neighbors. The telephone has evolved into a ubiquitous communication device, but it has not contributed per se to overcoming urban alienation. Sociologists such as Wellman (2001, 2002) and Wellman et al. (2003) describe how people construct their social networks with the help of the telephone and other devices. Wellman argues that, while people become more accustomed with the features these tools offer, the nature of the social ties that people establish and maintain changes from “door-to-door” and “place-to-place” relationships to “person-to-person” and “role-to-role” relationships. He creates a holistic theoretical framework that builds on the dual nature in the interplay between community and the individual. He describes the emerging qualities of this behavior as networked individualism.

Residential areas, such as apartment buildings, townhouse complexes, master-planned community sites, and the residents and tenants of these units form the focal point in this article to examine the interplay between people, place, and technology. The results and findings of this theoretical analysis will help to shed light on some aspects of the community question, especially the continued purpose and relevance of neighborhoods in urban habitation, by investigating the ironic relationship between endemic urban alienation and the widespread use of mobile and ubiquitous communications technology by urban dwellers that allows them to interact with each other (Walmsley, 2000).

Before this technology became ubiquitous and entered the everyday life of city dwellers, predecessors and variations had been designed for or had first become popular in workplace-based environments in order to support communication and collaboration among professionals. This was followed later by their diffusion into everyday life and their reappropriation for social use. The act of reappropriation (e.g., from the professional use of a pager to the social use of SMS) implies that there
are opportunities to design and develop purpose-built systems from the ground up, which, instead of merely trying to make ends meet, take the unique requirements into account of the social- and place-based context in which they are used. Tools to animate and network urban neighborhoods require a consideration and treatment of notions of sociability, place, privacy, and proximity in order to take full advantage of the communicative opportunities that this environment offers its inhabitants and the wider society.

PLACE MATTERS: COMMUNICATION AND INTERACTION IN URBAN NEIGHBORHOODS

Tönnies’ (1887) idea of community as Gemeinschaft implies a well-connected, place-based, collective, village-like community. However, this notion of community represents an overly romanticized image of community and ignores more contemporary forms of community that have been explored by recent sociological studies (Wellman, 2001, 2002). Gemeinschaft might resemble Hobbiton in the Shire described by Tolkien (1966). This communitarian notion (de Tocqueville, 2000; Etzioni, 1995) is still referred to frequently in the community development literature, although the homogeneous, egalitarian, and all-encompassing nature of Gemeinschaft is a utopian ideal that is less and less compatible with contemporary characteristics of community as social networks in today’s network society.

Before the advent of modern information and communication technology, human interaction was limited by the reach of the physical presence of self or the representations of self (e.g., letters and photographs) and available means of transportation. The need to socialize and to communicate was usually satisfied with family members in the same household, with friends and peers nearby, at work, or within the vicinity of the neighborhood people lived in. Human relations were door-to-door or place-to-place (Wellman, 2001). The fact that people residing in the immediate surroundings were known also established a feeling of security, community identity, and a sense of belonging — a feeling that clashes with the experience of living in today’s high-density, compact urban environments.

The invention and introduction of new information and communication technologies into society has usually been accompanied by foresights that predict that people will be less dependent on place and location. To an extent, this is true. The phone was the first major invention to introduce personal telepresence and to allow everybody to communicate in real time with others outside their own physical locality. Instead of being restricted to people within proximity of oneself, the phone enabled long-distance communication to maintain work and social relationships. However, it is unlikely that anyone lifts the telephone handset to introduce themselves to a neighbor nearby that they have not met before.

The Internet affords both synchronous and asynchronous applications that enable communication between one or multiple users, one-to-many or many-to-many broadcasts to a closed group, and public announcements to an open audience. The abstract nature of Internet-mediated communication gave rise to the widespread use of the metaphor cyberspace, which visualizes the emergence of a new spatial dimension.

However, people’s bodies cannot be atomized in the same way that their audiovisual representations can be digitized, mediated, and sent across the world. Thus, people depend and will continue to depend on place and locality and on co-located face-to-face interaction. Bits and bytes travel in the virtual space of flows spanned by the Internet, but humans travel in the physical space of flows that modern transportation affords. Place and proximity continue to matter in every socioeconomic context, because there are no Internet applications that can completely substitute
Analyzing the Factors Influencing the Successful Design and Uptake of Interactive Systems

real-time, co-located, face-to-face interaction. This is evident by rising car and air travel sales (Wellman, 2001), by people commuting to work instead of working from home and by the formation of economic clusters, precincts, and hotspots where industries based along the same value chain co-locate to take advantage of synergy effects. Florida rightly argues that “the economy itself increasingly takes form around real concentrations of people in real places” (Florida, 2003, p. 4). In light of new urbanism (De Villiers, 1997) and master-planned residential community sites (Gleeson, 2004), his statement holds true not just for the economy but for society, in general.

Attempts to bridge distance for the purpose of more than just communication have seen initiatives such as telework and distance education, yet they remain at the edge of mainstream usage and have not replaced face-to-face interaction (Dhanarajan, 2001; Gillespie & Richardson, 2004). To enable economic efficiencies, the goal of Computer Supported Co-operative Work (CSCW) and groupware applications is to supplement not substitute place-based work practices.

Wellman (2002) points out that the dichotomies of physical place and cyberspace or of online and off-line are misleading. Even as the Internet grows exponentially, place-based units such as home, work, and school remain at the core of our understanding of everyday life. The Internet and other information and communication technology add new qualities to the portfolio of communication tools available to us, enriching our communicative ecology and adding on to the variety of media channels at our disposal. We do not rely on the central location of traditional meeting places anymore, such as the marketplace or town square, in order to meet with friends and peers. Instead, we use mobile communications technology that we can carry around (e.g., mobile phone, SMS) or ubiquitous communications technology that we can access anywhere (e.g., wireless networks) not to avoid but to negotiate on-the-fly meeting places and venues anywhere and anytime. Teenagers, for example, use their mobile phones to arrange meeting places on the spot; this could be the local café, the shopping mall, or someone’s home (Satchell, 2003). This emerging behavior introduces challenges to conventional understandings of place and public places and opens up opportunities for residential architecture, town planning, and urban design (Castells, 2004; Florida, 2003; Grosz, 2001; Horan, 2000; Mitchell, 2003; Oldenburg, 2001; Walmsley, 2000).

In a lively online discussion about the continued purpose and relevance of neighborhood communities, one participant (eric_brissette, 2004) illustrates the point that having less exposure to neighbors (as opposed to coworkers or friends) does not mean that it is less likely that there are, in fact, prospective friends living in the neighborhood:

I guess it all depends on where you live. I live in a rural town of about 10,000. Most people say “hello” or “good morning” to you as you pass them on the sidewalk. I can’t say I’ve known all of my neighbors well, but I have at least spoken with them enough to know a bit about who they are. Visiting larger cities like Boston or New York makes me feel weird. Nobody looks you in the eye, and everyone seems constantly pissed off, almost like everyone is scared of everyone else ... yet this all seems perfectly normal to them. ... Chances are good that there are people in your neighborhood that share your [interests] or are at least [compatible] at the personality level who you wouldn’t normally interact with on a daily basis.

In today’s networked society, it is questionable to project the image of the rural village and use it as a best practice urban village model for a city because of inherent differences between both places and their inhabitants. Yet, the specific characteristics of a city can give rise to a different model of urban village that acknowledges the potential opportunities that this particular environment offers its residents. For example,
the simple fact that a city accommodates a larger number of residents could offer the individual greater choice and, thus, a chance to find the right social interaction partners.

However, the motivation for and process of the search itself remains to be examined. Getting to know someone in their role as a neighbor is less likely than getting to know them in their role as a coworker or being the friend of a friend. Neighbors may still be part of a resident’s social portfolio, but the communication devices used to maintain these ties are inherently place-independent and ephemeral: A phone call or an e-mail does not distinguish between close or distant friends. Proximity does matter when it comes to physical encounters and face-to-face meetings. Most frequent social ties, including online interaction, are maintained with people who can easily be reached physically; that is, they usually reside within the same city, the surrounding suburbs, or the same neighborhood (Horrigan, 2001; Horrigan et al., 2001). The majority of phone calls, SMS, and e-mails helps the parties involved to coordinate meetings or social gatherings (e.g., to catch up over coffee in a café nearby).

These ties are based primarily on common friendship, workplace, or interest, and not on shared locality. We may be introduced and subsequently get along well with the friend of a coworker who happens to live on the same street, but it is unlikely that we would have found out about that person without the coworker introducing us first.

Many urban neighborhoods are the result of what town planners and developers call master-planned communities. Traditional conceptual models of community development limit action to tangible places of public interaction such as kindergartens, public schools, parks, libraries, and so forth (Gleeson, 2004). This build-it-they-will-come approach lacks engagement with the findings of recent community development research (Gilchrist, 2004; Pinkett, 2003). It ignores both the human factors involved in urban renewal and sociocultural neighborhood animation as well as the potential that information and communication technology can offer urban residents such things as online community networks and location-based new media (Day & Schuler, 2004; Rheingold, 2002).

Gilchrist points out that “community development involves human horticulture rather than social engineering” (Gilchrist, 2000, p. 269). Social encounters in urban neighborhoods cannot be master planned. They are based on coincidence and serendipity. Neighbors meet through friends of friends, who happen to live close by; they meet when walking the dogs or, in some cases, when a local problem affects multiple residents (Hampton, 2003). However, more often than not, they do not meet at all, and even if they wanted to, there is usually little opportunity beyond serendipity. Our preliminary results indicate that the majority of residents surveyed believe, just like Eric, that chances are good that there are people in their neighborhood who share their interests or with whom they are at least compatible at the personality level, people they normally do not interact with on a daily basis. For those who would like to find out about them and who still believe in good neighborhood relations, the question remains: What can be done to avoid relying on good fortune and fate? How can those who want to, coax luck?

A step toward a more strategic approach to develop urban neighborhoods encompasses online community networks (Schuler, 1996). Community networks are integrated online systems designed for residential communities that, so far, have usually been comprised of communication tools such as mailing lists, discussion boards, and newsletters. Ideally, community networks allow residents to communicate and interact with other users and to take advantage of the proximity to other residents in the neighborhood. Thus, these systems have the potential to build a bridge between virtual public spaces and physical public
Analyzing the Factors Influencing the Successful Design and Uptake of Interactive Systems

places and to foster network social capital and neighborhood identity.

COMMUNITY NETWORKS IN URBAN NEIGHBORHOODS

Arnold (2003) states that “for the ordinary citizen, social interaction is the ‘killer application’ of the Internet” (p. 83). This development has sparked an increased interest among researchers from a range of disciplines to investigate online communication and online communities (Preece, 2000). Yet, the majority of the work undertaken so far in this research field focuses on globally dispersed online (virtual) communities and not on the use of information and communication technology for communities of place (Papadakis, 2004).

There is a small but growing body of literature that reports on the use of information and communication technology for community development in place-based contexts, mostly within the emerging discipline that Gurstein (2000, 2001) terms community informatics. However, most of these accounts investigate communities that are in one way or another deprived (e.g., telecenters or community access centers in rural and remote locations; ICT for development and poverty reduction in developing countries). The transferability of these studies to urban settings is questionable. Urban dwellers may think of themselves as being quite well-off and may lack common disadvantages, such as low income or unemployment. Such instances of deprivation could contribute to shared agony, which ultimately may help to establish a collective need for change (Foth, 2004b) and, thus, a reason to make use of technology for action and change. In its absence, however, alternative motivations to form neighborhood community need to be found.

Today, the value of door-to-door and place-to-place relationships in urban neighborhoods seems to be on the decline. Researchers and practitioners endeavor to counter this trend through community networking; that is, the application of Internet-and Web-based tools in residential environments to introduce and sustain local communication and interaction among neighbors (Day, 2002). Although the term is sometimes used broadly in other contexts of community development and community informatics, the focus in this article is on urban neighborhoods.

A residential community comprises people who live or stay in a geographically demarcated area. Such communities are sometimes also referred to as local communities, physically or geographically based communities, or communities of place. Apart from the fact that members of a residential community share the same location or address, they are not bound necessarily by any other common characteristic such as interest, age group, or occupation. As such, residential communities are not communities or neighborhoods a priori. An apartment complex might consist of residents who do not know each other.

A range of research projects have been undertaken to examine whether online community networks can facilitate the process of establishing neighborhood identity. These projects set out to design and implement online community networks for both large and small residential sites with various aims and with varying degrees of success (Arnold, 2003; Carroll & Rosson, 2003; Cohill & Kavanaugh, 2000; De Cindio et al., 2003; Hampton & Wellman, 2003; Meredyth et al., 2004; Pinkett, 2003).

Reaching a critical mass of users is considered to be one of the key criteria of success (Arnold et al., 2003; Butler, 2001; Patterson & Kavanaugh, 2001) and has been reported as one of the most common stumbling blocks: “If you build it, they will not necessarily come” (Maloney-Krichmar et al., 2002, p. 19). This statement seems to be common sense; nonetheless, it provides the opportunity for a deeper analysis of the reasons and motivations for urban residents to communicate,
interact, and get together with other residents and to participate actively in an urban neighborhood network.

Dunbar (1996) suggests that the size of human social networks is limited for biological and sociological reasons to a value of around 150 nodes. Barabási (2003) and Watts (2003) provide a more far-reaching overview of recent advances in network theory and their impact on business, science, and everyday life. Some ideas are crucial in understanding community networks: They usually increase or decrease in size, that is, social network research and systems design need to find ways to capture their dynamics. Their structure is not random or chaotic but follows preferential attachment (rich get richer) and fitness (fit get richer). In the context of communities of place, Jankowski and his colleagues support this thesis with empirical research by pointing out that “those geographic communities already rich in social capital may become richer thanks to community networks, and those communities poor in social capital may remain poor” (Jankowski et al., 2001, p. 113). Hampton & Wellman (2003) support this notion by stating that “connectivity seems to go to the connected: greater social benefit from the Internet accrues to those already well situated socially” (p. 283). Then, the next questions are, what constitutes richness and fitness in urban social settings, how do residents get rich (and become a hub in their social network), and how can community networks facilitate enrichment in a fair and ethical manner?

The reasons and motivations for participation in dispersed online (virtual) communities provide further insight into the answers to these questions. A person suffering from cancer might prefer the expertise, empathy, and perhaps anonymity available in an international online community of cancer patients. Philatelists will find more like-minded people in an appropriate virtual community of interest, such as a newsgroup or discussion board that is open to any Internet user and that is not restricted to the residents of just one apartment complex or one suburb. The impossibility or impracticability of a face-to-face exchange in a dispersed online community does not usually impact negatively upon the value that participants derive from such online interactions. The large number of active online communities tells its own tale.

The core characteristic of such dispersed online communities is their collective nature; that is, they accumulate participants who share a common interest, profession, or support need with an entity that acts as a collective group with a shared purpose. The tools that are used to support online communities, including mailing lists, newsletters, discussion boards, and so forth, are more closely designed toward a many-to-many broadcast approach instead of a peer-to-peer networking approach. They assume a pre-existing motivation to participate in and use the virtual space. In the case of shared interest, profession, or support need, that may be the case. However, in the case of residents of urban neighborhoods, the only shared attribute is place and colocaiton. Apart from occasions where an item of discussion or a topic of interest relates directly to the shared place that residents coinhabit, most interaction is located within place but not necessarily about place. Thus, place and proximity are insufficient attributes to attract residents to a community network and to sustain it. Furthermore, a reappropriation of the tools used to support online (virtual) communities in the context of urban neighborhood networks opens up further issues, because a community of place is inherently different from a dispersed community of interest. In addition, connectivity per se does not ensure community, and proximity does not ensure neighborliness (Foth, 2003, 2004b).

The unique selling proposition that could give online community networks for urban neighborhoods a competitive advantage over dispersed online communities is proximity. Community networks allow residents to interact online and to take and continue online interaction off-line, in
Analyzing the Factors Influencing the Successful Design and Uptake of Interactive Systems

real life, and face to face with other residents who live in the same location. As such, they can be an effective tool for local community engagement and activism, if the community faces a shared problem or a common enemy that provides the required motivation for residents to come together. Hampton (2003) describes the experience with residents in Netville, who faced the prospect of losing broadband Internet access, which previously had been provided to them free of charge. The issue and the presence of a common enemy; that is, the Internet service provider, unified residents in community activism to advocate for a continuation of the service, and the traffic in the online community network (in the form of an electronic mailing list) increased significantly. The unifying vigor of a common problem or issue can (temporarily) transform a certain number of residents into a residential collective and, thus, sustain an online community network (Foth & Brereton, 2004).

In the absence of a common enemy, a shared purpose or a pre-existing village-like atmosphere, are there other reasons and motivations for social encounters to occur and for the formation of residential networks in urban neighborhoods? Examining existing urban communities may help to answer this question. Watters (2003) describes the emergence of clusters of under-35-year-old urban dwellers mostly in America but also in other parts of the word as urban tribes. They represent a social network, a swarming group of friends who live in the same city and who are all connected with each other through strong and weak ties. The interaction between members of urban tribes is facilitated through the use of mobile phones, e-mail, and face-to-face gatherings. Watters (2003) does not mention the use of neighborhood or similar ICT-supported networks, but his account of the behavior of urban tribes allows one to imagine a new generation of purpose-built interactive community networks for residents in urban neighborhoods.

THE URBAN TRIBE INCUBATOR: NETWORKING SERENDIPITOUS SOCIAL ENCOUNTERS IN URBAN NEIGHBORHOODS

The previous section discussed the conditions under which residents might ultimately engage in neighborhood community networks and, thus, talk to people within their vicinity. In order for these conditions to emerge, competitive tools need to be designed that allow residents to find out who is living around them and that facilitate local communication and interaction that so far has relied on coincidence and serendipity. However, conventional community networks do not necessarily address these needs. They are very delicate, organic entities. They thrive only in favorable circumstances (e.g., similar demographic and professional orientation) with special nurturing (e.g., free Internet access) (Hampton & Wellman, 2003; Kavanaugh et al., 2003), and chances are high that, otherwise, they may fail (Arnold et al., 2003).

The findings of these sociological studies provide essential insights for a new design methodology that can guide the successful development of interactive systems and devices that can stimulate local interaction and animate urban neighborhoods. A prototype system of an urban tribe incubator is currently being developed and tested in three urban residential sites in Australia (Foth, 2004a). Action research (Hearn & Foth, 2005) and participatory design (Churchill et al., 2004; Greenbaum & Kyng, 1991; Schuler & Namioka, 1993) play crucial roles in iteratively constructing and testing a successful prototype. The participation of residents in the design and development is essential to integrate the range of communication channels that they use and to allow residents to take social ownership of the system.

The previous discussion of the factors influencing systems that support social networks in urban neighborhoods gives rise to a set of design
Analyzing the Factors Influencing the Successful Design and Uptake of Interactive Systems

considerations that are being integrated into the design of the urban tribe incubator prototype. These are now discussed in turn.

**Size, Growth, and Critical Mass**

Popular services and functions in conventional community networking systems include electronic newsletters, mailing lists, and discussion boards. In order to keep these systems interesting and appealing, content needs to be generated either by a systems administrator or a delegate but ideally by the community of users itself. Thus, a critical mass of users is required to maintain an ongoing supply of discussion board postings and responses, mailing submissions, and newsletter contributions. It requires residents to invest a reasonable amount of time and effort in order to collectively sustain the system’s viability.

The urban tribe incubator may include such collective, broadcast-style, many-to-many functions, but the core will be a residents’ directory that does not require maintenance on a regular basis, unless details have changed and need to be updated. A resident’s personal profile may comprise information about skills, trade, interests, hobbies, and contact details. The profile becomes the virtual representation of a potential node that invites other residents to link to and from. The system does not require users to use the directory on a regular basis in order to interact with all other users. Rather, the system allows users to opt in and opt out as they please and as a need arises by facilitating personalized networking; that is, voluntarily initiating contact and building social ties with people of their choice. Thus, the directory becomes the catalyst for personalized peer-to-peer social networks to form.

The size and growth of the directory itself is in no linear relation to the size and growth of an individual resident’s social network. The system acknowledges different levels of social richness and fitness, and thus, the point of saturation remains a personal preference. If an individual’s personal limit of social saturation is reached, he or she can opt out. In conventional community networks, for example, users usually cannot control how many people will respond to their posting on a discussion board: It may be none, or it may set off an avalanche of responses. In an instant messenger application, however, users remain in control of the social network with which they engage — their private buddy lists.

**Diversity, Individualism, and Choice**

The urban tribe incubator is not designed to host an online community of a particular interest or support need but rather allows for the diversity of individual residents with different interests and support needs to find each other and to form smaller social clusters. The system presents residents with choice in relation to the number and characteristics of communication partners and modes of interaction. It provides easy and convenient ways for residents to identify “birds of a feather”; that is, to find like-minded people with common interests or support needs.

The system raises awareness among residents of who is living around them in order to facilitate peer-to-peer connections. The resident directory that links to individual profiles allows residents to choose what personal information they publish online or whether to keep certain information private or only available upon request. The goal of a resident directory is not to facilitate residents initiating virtual contact first (although it can be used in this way) but rather to simplify the process of strengthening serendipitous social encounters that happen while “walking the dog.” Without an urban tribe incubator, such informal contacts that have the potential to develop into rich interaction may remain superficial and transitory.

The system does not require residents to keep communication within the system but allows them to move it to other synchronous or asynchronous communication platforms and devices. Having access to an online directory, a resident is able to
maintain contact with a new acquaintance and to integrate this contact into their established usage of existing personal peer-to-peer communication devices, such as instant messenger, e-mail, SMS, and online chat.

**Privacy and Social Control**

In order to safeguard privacy, residents have control over their personal information and the scope of their online engagement. Enhanced local sociability is welcomed by most residents but must not come at the cost of losing security and control of the voluntary and selective nature of one’s social networks. Our preliminary results are encouraging insofar as residents seem to be trusting their (yet personally mostly unknown) neighbors with personal details such as name, phone numbers, e-mail addresses, photo, occupation, interests, hobbies, and so forth. In our survey, the majority of residents indicated that they are willing to share this kind of personal information online with other residents in the building.

Nevertheless, issues of privacy and social control have to be translated into appropriate terms and conditions that govern the usage of the system and the interaction among residents of the building. It is imperative to ensure that residents have the chance to opt in and opt out at any time without missing out on any essential information. Hence, it is worthwhile to consider supplementing official online communication channels with public announcements on neighborhood pinboards in prominent places within the building (e.g., parking lot entry, reception or entrance area, manager’s office door, elevators) in order to provide alternative ways to access community information.

**Network of Networks, Identity, and Sense of Belonging**

The urban tribe incubator may resemble more the networked nature of, for example, an online dating site than the collective nature of, for example, an online discussion board. What may emerge from this process of personalized networking (or online dating) is a complex web of social networks that span the anonymous void of the building complex, a web of urban tribes (Watters, 2003). Social hubs will continue to play a crucial role as their bridging links (Kavanaugh et al., 2003) connect different social networks and establish connectivity in the sense of community and solidarity. Drawing on viral marketing strategies (Godin, 2001; Goldsmith, 2002), the incubator allows individuals to cross-invite and introduce peers to the other networks in which they participate, both inside and outside the neighborhood. The feeling of a neighborhood identity and a sense of belonging can only emerge if bridging social links between members of different urban tribes contributes to the formation of a mesh-work of urban tribes that is “networked to the ‘edge of chaos’” (Gilchrist, 2000, p. 264). In this context, identity and a sense of belonging are not derived from the collective feeling of being co-located in the same place but from the feeling of being connected to a group of friends who are part of a greater group of peers living close by.

**CONCLUSION AND OUTLOOK**

The design considerations presented here will guide the development of the core prototype system. We then envision to extend this core with more sophisticated features that, for example, allow users to produce and to exchange creative content (photos, audio, video) through sociocultural animation (Foth, 2006) and that simplify the tasks of organizing and managing social gatherings, such as calendaring, inviting, RSVPs, synchronizing with SMS and e-mail, and so forth. As well, in this environment, the social aspects of the urban tribe incubator can be combined with managerial features that allow apartment owners to interact with the body corporate and tenants with the
on-site management. In this role, the system can manage rates and rent payments, entry notices, mailings and notifications, personalized information on contractors, and house rules, thus adding further value to the system and encouraging uptake and usage. Cross-platform compatibility is key. As such, the urban tribe incubator is anticipated to be a technical framework that can be accessed not only on the home or office computer but also on mobile and other devices.

The future holds interesting outlooks for platform developments. New urbanism, urban renewal, and the move toward more and more compact cities create opportunities to rethink the communicative paradigm of apartment complexes and vertical real estate as well as the sociological qualities of the office environment in which most social software is accessed. The kitchen is associated with the preparation of food, which is an essential part of one’s social life, as opposed to the office, which is the center of professional life. Hence, modern residential architecture often links the kitchen area with the living room in order to form one seamless space that can be re-purposed for entertainment and leisure. In this context, the much-scorned Internet fridge might see a revival as an integrated local communication hub that combines the functionality of a simple touch-screen display interface, a ubiquitous instant messenger, and a synchronized resident buddy list with location-aware services and groupware functionality. The rationale for choosing the fridge is not based on the inherent cooling functionality of the fridge itself, but its position and prominence within the environment of many urban homes.

The article contributes to substantiating a new zeitgeist of designing residential community networks for urban neighborhoods, which is characterized by combining current understandings of social networks inherent in Wellman’s theory of networked individualism with the affordances of ubiquitous communication devices and applications for personalized place-based networking such as the Internet, instant messengers, and mobile phones. Putnam (2000) argues that “the Internet will not automatically offset the decline in more conventional forms of social capital, but that it has that potential. In fact, it is hard to imagine solving our contemporary civic dilemmas without computer-mediated communication” (p. 180). If online community networks for residential communities are designed to include features that cater to both collective and network interaction, then they have the potential to contribute to the creation of neighborhood identity and to increase network capital and social capital in urban environments (Florida, 2003; Huysman & Wulf, 2004; Quan-Haase et al., 2002; Watters, 2003). Thus, they may prove to be a milestone in the quest to animate urban neighborhoods, to revive forms of civic engagement in society and to enact global connectivity for local action, in order to move from the vision of the global village to a new understanding of the urban village.

ABSTRACT

This article describes a study clarifying information systems (IS) designers’ conceptions of human users of IS by drawing on in-depth interviews with 20 designers. The designers’ lived experiences in their work build up a continuum of levels of thought from more limited conceptions to more comprehensive ones reflecting variations of the designers’ situated knowledge related to human-centred design. The resulting forms of thought indicate three different but associated levels in conceptualising users. The separatist form of thought provides designers predominantly with technical perspectives and a capability for objectifying things. The functional form of thought focuses on external task information and task productivity, nevertheless, with the help of positive emotions. The holistic form of thought provides designers with competence of human-centred information systems development (ISD). Furthermore, the author hopes that understanding the IS designers’ tendencies to conceptualise human users facilitates the mutual communication between users and designers.

INTRODUCTION

As information systems (IS) increasingly pervade all aspects of everyday life, of utmost importance is how applications of IS are adjusted to human action. In particular, in current information systems development (ISD) it is essential to take into account human characteristics and behaviour; that is, to humanise IS (Sterling, 1974). In the same vein, Checkland (1981) argues that ISD should be seen as a form of enquiry within which IS designers’ understandings regulate an operationalisation of their intellectual framework into a set of guidelines for investigation that require
particular methods and techniques for building the system. Regarding the humanisation of IS, a notion concerning the nature of the human being is a crucial element of the intellectual framework. As a consequence, within this kind of enquiry, the way humans are taken into account in ISD is dependent on the operationalisation of the IS designers’ conceptualisations of users. With respect to human-centeredness, attention should be paid to the fundamental qualities of people without any explicit or implicit domination of the other elements of IS, such as data, formal models and technical appliances, or managerial belief systems that treat humans instrumentally. This is necessary in order to conceptualise humans in their own right, and thus avoid the reduction of humans to something that exists only in relation to particular instrumental needs and purposes (cf. Buber, 1993).

Of essential importance is the nature of IS designers’ insights into human characteristics and behaviour that are essential with respect to the IS-user relationship. The most crucial insight regarding human-centred design is to be able to conceptualise users as active subjects comprised of physical, cognitive, emotional, social and cultural qualities, an insight which is the prerequisite for design that promotes subsequent user acceptance and satisfaction. Yet conspicuously absent from contemporary IS literature are empirical studies investigating IS designers’ conceptions of the human users, which have been studied more intensively two decades ago when the systems designers’ inadequate view of the user has been stated to be one reason for the behavioural problems often experienced while implementing IS (Bostrom & Heinen, 1977; Dagwell & Weber, 1983). Also, the lack of knowledge of human needs and motivation on the part of the systems designers has been claimed to cause IS implementation failures (Hawgood, Land & Mumford, 1978). Further, Hedberg and Mumford (1975) have defined the nature of the view of human being held by systems designers as an essential factor in the IS design process. The systems designers’ view of the user is also included in some studies as one of the targets of value choices during the ISD process (Kumar & Bjørn-Andersen, 1990; Kumar & Welke, 1984) and is therefore defined as a value rather than an insight in these studies. Dagwell and Weber (1983), in their replication study, rely on Hedberg-Mumford’s definition of the concept but also refer to Kling (1980), “we know very little about the perceptions that computer specialists have of the users they serve and the ways in which they translate these perceptions into concrete designs (p. 47).” Bostrom & Heinen (1977), in turn, define systems designers’ assumptions of people as one of the system designers’ implicit theories or frames of reference. These previous works do not take an explicit stance toward the definition of the concept “conception,” and do not align the nature of conceptions in detail. For instance, from where do conceptions derive their origins, and what is the nature of those conceptions? In a more recent study, Orlikowski and Gash (1994) discuss their definition of the IS designers’ views. They elaborate the concept “frame of reference” by comparing it to the concept “schema” (Neisser, 1976, pp. 9-11), “shared cognitive structures” or “cognitive maps” (Eden, 1992, pp. 261-262), “frames” (Goffman, 1974, pp. 10-11), “interpretative frames” (Bartunek & Moch, 1987, p. 484), “thoughtworlds” (Dougherty, 1992, p. 179), “interpretative schemes” (Giddens, 1984, pp. 29-30), “scripts” (Gioia, 1986, p. 50), “paradigms” (Kuhn, 1970, p. 43), and “mental models” (Argyris & Schön, 1978). They end up by defining their own meaning for the concept frames as a general concept of shared cognitive structures, not especially regarding humans.

This article describes a study which aims to clarify IS designers’ conceptions of users of IS by drawing on in-depth interviews with 20 IS designers. The analytical choices carried out in this study regard IS designers’ conceptions of users as experiences inherent in their lifeworlds, particularly during the different phases of ISD.
The lived experiences build up conceptions that form a structure of meaning, which incorporates a continuum of levels from more limited understandings to more comprehensive notions; that is, different levels of thought reflecting variations of the designers’ situated, practical knowledge. In this way the development of IS is understood as knowledge work. It is an intellectual and personal process which takes its form according to the conceptions of the performers of the process. IS designers are then applying the ISD methodologies according to their own observations and thinking (Avison & Fitzgerald, 1994; Hirschheim et al, 1995; Mathiassen, 1998). Then the most important tool for ISD, and a key resource in contemporary IT companies, is the IS designers’ thought and insight (Nonaka & Takeuchi, 1995; Quinn, 1992). Particularly with respect to the humanisation of IS, designers’ conceptualisations of the human users are seen as knowledge that reflects the designers’ competence in humanising IS. In this way, IS designers’ conceptions may be seen as intellectual capital that mirrors the know-how, practices, and accumulated expertise of practitioners within a particular profession (Kogut & Zander, 1992).

In what follows, first, the assumptions informing this study are presented by introducing the interpretative approach referred to as phenomenography. Second, the resulted forms of thought are presented and discussed. The IS designers’ conceptualisations presenting their mental schemes of the human user result in three forms of thought, revealing both context-centred and human-centred understandings of what humans are. These three levels of understanding indicate that IS designers tend to conceptualise uses in terms of technology, business and work, and that seldom are users taken into account according to their human qualities. Finally, the different levels of conceptualisation are discussed in relation to human-centred ISD.

DIFFERENT LEVELS OF UNDERSTANDING

This study merges with the principles of phenomenography, which is a qualitatively oriented method of empirical research for investigating the different ways in which people experience aspects of reality (Marton, 1981; Marton & Booth, 1997). Essentially, phenomenography is about individual meaning construction, which results in a conception. The primary focus is on the structure of the meaning of conceptions, which are seen in the light of the phenomenological notion according to which person and world are inextricably related through a person’s lived experience of the world (e.g., Husserl, 1995; Merleau-Ponty, 1962). Our intentionality is seen as qualitatively varying foci on the horizon of our life worlds.
Different Levels of Information Systems Designers' Forms of Thought and Potential

While experiencing the world, individuals form conceptions, including qualitative dissimilarities, which are inherent in the intertwined referential and structural aspects of an experience. Different levels are due to the way the structural aspect and the referential aspect merge with each other. Then an experience is specified by the analytical distinctions of a structural aspect and a referential aspect (Figure 1). The structural aspect denotes how a particular phenomenon is both discerned from its environment and how the phenomenon's parts relate to each other as well as to the whole phenomenon. That which surrounds the phenomenon experienced, including its contours, is its external horizon. The parts and their relationships, together with the contours of the phenomenon, are its internal horizon. The referential aspect signifies the meaning of the conception. These two aspects are dialectically intertwined and occur simultaneously within an experience. Thus, people create conceptions with respect to the structural aspect’s external and internal horizons of a phenomenon that are dialectically merged with the referential aspect of that particular phenomenon.

On the one hand, conceptions differ in terms of content, and on the other hand, they differ in terms of the extent of the form that a certain phenomenon is experienced, as a part of that phenomenon, or more as a whole. When detached parts of a phenomenon are the focus of thought instead of relating the parts meaningfully to the whole phenomenon, the meaning of the phenomenon is understood in a way that refers to a more narrow view. Respectively, when the focus of thought is more comprehensive regarding the whole meaning of a phenomenon instead of on separate parts of it or even the surroundings of the phenomenon, the more explanatory conceptions are. Further, the more explanatory power conceptions have, the better they support competent action with respect to the phenomenon in question (Sandberg, 2000). Based on these differences, conceptions form a structure of meaning, which incorporates a continuum of levels from more limited understandings to more comprehensive notions. The qualitative variation in the ways that IS designers conceptualise users reflects their different conceptions of users, and simultaneously forms different levels in the designers’ understandings, reflecting variations of their situated, practical knowledge as forms of thought. These forms of thought, in turn, suggest different levels of competence in humanising IS, because the subjective conceptualisations of IS designers refer to their intention of action (Säljö, 1994).

The interview method is accomplished with respect to phenomenographic principles. To promote multiple interpretations within individual designers, first, opening questions with varying perspectives into the different phases of ISD, such as planning, design, implementation, use and maintenance, was incorporated in the interview framework. Second, to sustain the connection between the designers’ reflection and the actual work within ISD phases while the in-depth interviews aimed at achieving mutual and authentic understanding that proceeded from the interviewees’ expressions. The interviews were taped at the designers’ workplaces to maintain the work practice orientation and to facilitate the expression of the connection between the respondents’ immediate experiences and the subsequent conception. Second, the respondents represent a variety of geographical location, age, gender, educational background and work experience. They came from various different application areas of IS practice, such as e-commerce, tele and media communications, groupware, health care systems, office automation and insurance systems.

The analysis of the interview data was carried out against the phenomenographical theory. Since phenomenography does not offer grounds for defining the content of conceptions within data, a coding paradigm was developed from the data in order to facilitate the identification and categorisation of meanings in the data (Glaser & Strauss, 1967; Tesch, 1990; Strauss & Corbin, 1990). The development of the coding paradigm was based
Different Levels of Information Systems Designers' Forms of Thought and Potential

on the phenomenographical principle regarding the intentionality of conceptions. Conceptions are context-dependent and every experience is described in content-loaded terminology (Säljö, 1994.). That is, the descriptions are carried out in terms of the nature of the situational experiences in question. Consequently, the meanings are to be found in accordance with the underlying assumptions concerning the intentional nature of ISD. In addition, since it is assumed in phenomenography that the meanings of the respondents’ mental acts exist in the data and are constitutive of the data (Walsh, 1994), the way meanings are understood in this study should also be in accordance with the types of intentionality existing in the data. Thus, the coding paradigm was finalised by bracketing away any preconceived ideas of what the IS designers’ views might be like (Francis, 1993), and letting the analysis be informed by the underlying assumptions of intentionality in ISD.

First, the data includes utterances that describe various actions and objectives concerning ISD. These expressions indicate intentionality as defined by Hirschheim et al. (1995, p. 16). They state that “IS development is intentional, to the extent it reflects a planned change. It is based on developers’ intentions to change object systems towards desirable ends”, and go on to say that (1995, p. 17) “intentions in systems development are expressed by objectives. These are related to general value-orientations and represent what ‘one ought to do’ or ‘what is good’.” From this it can be concluded, in the first place, that intentionality in ISD is expressed by intentional action. That is to say, IS designers’ descriptions of the actions and means they are involved with when developing an IS reveal the meanings they give to the phenomena they deal with concerning ISD. This notion is in accordance with the principle of contextuality in phenomenography, which denotes that people’s conceptualisations are not detachable, either from their context or the content of the task at hand. This stance also reinforces the interpretative nature of phenomenographical analysis in that the researcher must see the designers’ action as inherently meaningful (cf. Schwandt, 2000). In the second place, as Hirschheim et al. (1995) point out, intentions are expressed by objectives of ISD. Consequently, it is an appropriate way to define that the way the IS designers understand the human user of an IS is revealed through descriptions in which the respondents’ focus of reflection is on the objectives of ISD. That is to say, in addition to the actions and means the designers refer to, the IS designers’ intentions to change object systems toward desirable ends reveal the meanings they give to the phenomena they deal with concerning ISD. These desirable ends or objectives represent the things that are regarded most important in ISD. In this way, the IS designers’ descriptions of action, means and objectives also implicitly indicate value orientations included in the process of ISD. Therefore, the described actions and objectives represent the things that are regarded important, and thus reveal the referential aspect in terms of intentionality as an implied value orientation. This means that the initial referential aspects of conceptions may be found in utterances in which the designers refer to their way and means of building systems and the objectives of their actions.

Second, the data includes descriptions in which the respondents’ thoughts are attached to human objects. These descriptions of people indicated human features and also value orientations toward people. Often these descriptions also included expressions which indicated emotionally toned reactions. These kinds of expressions within the data indicate intentionality that is in accordance with Uljens (1991), who states that the process of qualitative individuation of a mental act has been done when an object and a psychological mode, referred to as an attitude, is shown. In other words, how a particular object of thought is experienced denotes the respondents’ attitudes toward the phenomenon that is being reflected on. In brief, the inherent meaning of an utterance may be seen as
the correlation between the what- and how-aspects in that they are not detachable from each other, but are interrelated in a particular logical way, indicating what a particular phenomenon is, in what it is revealed, and what kind of values and attitudes are related to it. As described above, the search for the meanings in the data, data analysis, was initiated by establishing a coding paradigm, which suggests that the meanings in the data are found in utterances in which the designers refer to their actions, means, and objectives concerning ISD, as well as to human characteristics.

The subsequent analysis procedures followed the idea, firstly, of iterating between the meaning (referential aspect) of single statements, their surrounding statements, and the data as a whole, and second, iterating between the features that reveal different levels in these meanings (structural aspect). The analysis appreciates the phenomenological notion of “Lebenswelt” in that the continuum of levels from more limited forms of thought to more comprehensive understandings reflects associative connections within the designers’ conceptions rather than direct, law-like logical relations between them (cf. Husserl, 1995). The analysis revealed the designers’ conceptions as different levels of understanding, which appear as the separatist, functional, and holistic forms of thought. These forms of thought reveal three different levels of understandings incorporating both context-centred and human-centred notions. In the descriptions associated with the context-centred conceptions, the designers’ focus of reflection is on technology, work, and business. The human-centred conceptions deal with knowledge, emotions, and the designers’ selves. The following description delineates the specific contents of the conceptions as parts of the three forms of thought by highlighting some exemplary conceptions.

**THE SEPARATIST FORM OF THOUGHT**

The most partial way in which the IS designers conceptualise humans is through the separatist form of thought. It demonstrates how IS designers see humans within the affordances and constraints of contemporary IS and their development as separated from fluid and coherent interactions. Within this form of thought, the user is positioned outside the IS designers’ awareness through objectivist conceptualisations. An objectivist pattern is evident in the context-centred separatist conceptions, which reflect understandings according to which reality exists independent of humans and can thus be understood independent of humans (cf. Lakoff, 1987; Orlikowski & Baroudi, 1991). In this case, when discussing human-centred issues of ISD, the designers’ focus of reflection is directed to technology, job titles, and market mechanisms. For example, within the conception of “the human being displaced by technology” IS designers refer to humans in terms of technology:

R: What are these requirements and wishes like? Could you tell me more about them?
D16: Well, because it is a question of – let’s say — a feedback channel that our company offers as a product to its clients, it means that if the client purchases, for instance, a datanet-based customer network, they have datanet and router accesses through which they operate between their networks and use the whole telecommunication network. Then there are a lot of this kind of usability issues, response times and load percentages, or in a way, how it (telecommunication network) sort of behaves, what happens there.

In the above interview extract, the designer considers the customers’ needs as a piece of software — “a feedback channel” — and the main point that emerges is how this item of software works with the functions of a telecommunications network. The designer’s train of thought becomes...
focussed on technology instead of human-centred issues and needs, such as how the software is built in regard to the humans that will be using it. In the same vein, within the conception of “the human being as a market” the designers make use of expressions which show their intention is to build products that are profitable and, therefore easy to sell. Yet they do not base their intentions upon human features, such as spontaneous and mood-related online behaviour that could be a prerequisite for selling their products (e.g., Hoffman & Novak, 1996; Bellman et al, 1999):

**D5:** It is more reasonable to develop a mass product which has a lot of users. The point here is that then it can be copied and sold.

In contrast to notions that emphasise understanding human consumption behaviour, the IS designers adhere to the idea that humans are simply a featureless mass of consumers who form a market for IT products. Because the above conception does not incorporate any human characteristics, but refers to a mass market, it is thereby making a clear distinction between the market and the features of the people assumed to form that market. For this reason, the conception appears as objectivist. This conception also implies a predisposition according to which the current development of IS as an industry is that of a rational institution which produces mass culture by reducing humans to members of a mass (cf. Slater, 1997). Furthermore, humans become separated attitudinally from IS and their development due to a presumed lack of technological knowledge, and thus are forced to encounter disparaging attitudes. The separatist human-centred conception of “the technology-illiterate human being” produces accounts according to which the most distinct characteristic of humans is that they are ignorant of technology, specifically computers, software and ISD methodologies. In particular, this illiteracy is seen as a contrast to the literacy of the IS designers:

**R:** Have you ever wondered why people behave in that way — that they cannot say what they want from the system?

**D17:** I think that it’s because they don’t know how these [IS] are defined. If one doesn’t know these methods, one can’t do it. That is the biggest reason, not that they aren’t willing to say what they want but they don’t have the know-how.

Beath and Orlikowski (1994) report similar findings in their analysis of a relatively new representative of the ISD methodologies’ rationalist tradition, information engineering (IE). According to the analysis, the IE text creates and sustains both implicitly and explicitly a dichotomy between users and IS designers by characterising the users as technologically ignorant in regard to the use of technology. When operationalised, these characterisations are likely to generate nonviable and unsatisfactory interactions between users and IS designers. It seems also that the designers do not consider the weaknesses in users’ knowledge and thought as an issue that deserves to be taken into account in design. However, when humans are included in the design considerations, the weaknesses in people’s thinking should be understood as natural flaws in human cognitive behaviour that can be appropriately guided, or even prevented by adequate design (Kirs. Pflughoeft, & Kroecck, 2001; Norman, 1989; Robillard, 1999). The idea then is that designers should have awareness of and be able to recognise these erroneous tendencies in users in order to carry out IS planning and design with the express aim of preventing people from committing faulty actions during computer use, rather than conceptualising users as technologically ignorant.

Moreover, negative emotions and physical stress symptoms have the effect of separating humans from IS. The conception of “the computer anguish human being” reveals views acknowledging that IS cause negative emotional arousal in users. These reactions are manifested as negative attitudes, resistance, fear and discomfort in
situations where people are confronted by plans for the future use of computers or in situations in which individuals are using computers:

**R:** How in your mind do people learn to use software?
**D6:** ... I have also met users who have so much fear of the user interface that they don't dare to explore or try anything, they just do what is familiar and safe.

These conceptualisations are consistent with statements concerning the widespread existence of technophobia (Brosnan, 1998a). Besides being an obviously unpleasant and undesired experience, negative emotions, such as anxiety and fear, make people’s behaviour withdrawn and elusive by narrowing their action (Fredrickson & Branigan, 2001), as well as decreasing the quality of their performance (Brosnan, 1998b).

In brief, within the separatist form of thought, the human being becomes separated from viable interactions with both the IS designers themselves and IS. This is due to a tendency to an objectivist conceptualisation, which blurs the designers’ thought to such an extent that people are no longer recognised as humans. The overall narrative style of this form of thought is reminiscent of the style of a nomothetic science reflecting technical, strategic views aiming at controlling the IS-related social system with the technical system (cf. Deetz, 1996). Further, people become separated from the development of IS due to disparaging attitudes inherent in designers’ assumptions that users are technologically ignorant. Moreover, this form of thought brings to the fore human characteristics, such as negative emotions, which are seen as an obstacle to a viable IS-user relationship.

**THE FUNCTIONAL FORM OF THOUGHT**

The functional form of thought consists of conceptualisations in which humans are seen to act in an insubstantial manner, adapting to the external functions of technology, work tasks and the way the IS designers themselves use computers. Within this adaptive response, positive emotions are required in order to create and sustain viable interactions with IS. In this way, the IS-user relationship is seen as functional: the action of people is seen as determined by their external environment, and the role of human emotion is to facilitate this process. The different conceptions that build up this form of thought reveal a behaviourist understanding of the human being.

For instance, the conception of “the invisible human being” denotes humans as using IS in an insubstantial manner. Typical of this conception is the belief that there is a user who uses an IS. Yet the user is not characterised further but is assumed just to use the system:

**R:** If you think of a situation where you are creating an application, who do you think you’re making it to?
**D16:** Hm....

**R:** Do you think of certain types of people or how does it show that you are making it for people?
**D16:** I don’t think of particular types of people but I think that the human being is in some sense always a part of the system. If it is a system that has a user interface so there must be somebody who uses it. Even if it is a system that runs by timer initiation, there must be a user interface, too, for setting the timer parameters in the system, so there must be somebody to use it, too. To my mind there is always someone using the systems, they (systems) are not fully automated.

A functioning relation between people and IS is thus acknowledged, but this does not include any features originating from the mental, social
Different Levels of Information Systems Designers’ Forms of Thought and Potential

or cultural human modes of being. In other words, humans and their behaviour are understood as purely physical-organic responses to technology, as established in the tenets of Skinnerian behaviourism (Skinner, 1938, 1991). Similarly, the IS designers’ conception of “the human being behind the process of work” denotes humans in conformity with behaviourist thinking. Within this conception individuals are seen in terms of their work tasks or organisational work processes. Characteristic of these conceptualisations is that the people performing the tasks are not portrayed further, but are assumed merely to use IS according to the external task flows:

R: How would you define users’ needs?
D8: They consist of the utilising organisation’s needs at all levels, beginning with what the people need in order to continually do their work tasks, and ending with the things that the organisation expects from the system, what can be abstracted from the process and be used to develop and control action.

Here, human action is seen as a series of direct responses to external work tasks issued to people. Zuboff’s (1988) well-known distinction between “automating work” and “informating work” highlights the difference between implied behaviourist and nonbehaviourist assumptions concerning human action in computerised work (pp. 9-10). Automating work refers to deploying technology in ways that increase the self-acting and self-regulating capacities of technical systems, which are expected to minimise human intervention. Because human intervention is minimised and machines perform the work tasks, interactions between individuals and computers become determined by the structure and sequence of computerised workflows to which, in turn, humans are supposed to respond. Zuboff’s term of automating work, thus, implies a behaviourist assumption of humans and their behaviour.

Quite the opposite is suggested by the term informing work, which adds to the automating view of work in that information technology can be used to automate, but at the same time, it has the ability to translate the automated activities into a form that renders work processes, objects, events and behaviours visible, knowable and sharable for people (Zuboff, 1988). That is to say, within the interaction of humans and computers, people actively observe, interpret and share the information which is mediated to them by IS. They do not just respond like marionettes to the information offered by IS, but actively construct their own conceptions of the computer-mediated tasks they are given and act according to their own interpretations of the particular situation. Thus, in order to accomplish fluid and coherent interaction designs between humans and computers in regard to particular tasks, the users’ mental models, especially those concerning the tasks submitted to them, should also be designed (Norman, 1989; Preece, 1994).

Also typical of the functionalist form of thought is that the role of human emotion is to facilitate people’s adaptation to technology. Within the conception of “The techno-enthusiast human being” the designers depict positive emotions, such as enthusiasm, as essential features in humans:

R: Do you think there are common features in those people for whom you have built systems?
D17: Well, at least during very recent years, it has been enthusiasm.

In particular, positive emotional reactions in people are seen to be induced by technology. Positive feelings are especially seen as a prerequisite for the successful use of IS. These conceptualisations reveal a functional understanding of positive emotions. Whereas negative emotions are associated with specific tendencies, such as an urge to escape or to avoid disquieting things, positive emotions seem to spark changes
in cognitive activity in addition to producing behavioural tendencies (Fredrickson & Branigan, 2001). Therefore, the IS designers’ accounts of positive emotions as a prerequisite for the use of computers imply an understanding of the role of human emotional features in promoting successful functioning.

To sum up, within the functional form of thought humans and their behaviour are understood from a behaviourist stance, which renders human substance only as physical and organic by nature, denoting that the movements of people can be explained by the laws of mechanics (Wilienius, 1978). However, this form of thought adds to the previous separatist way of thinking in so far as humans are actually depicted as performing tasks with computers, whereas in the separatist form of thought the conceptualisations either totally omit human features or humans are seen as unable to use computers. In addition, the human emotional feature that is recognised in this form of thought appears as positive — even though functional — in nature. This way of thinking acknowledges humans as users, and therefore is more developed than the previous separatist form of thought.

THE HOLISTIC FORM OF THOUGHT

The most developed form of thought by which the IS designers conceptualise humans as users of IS is the one characterised as holistic. Its holistic quality is revealed in several ways. First, unlike the preceding forms of thought, the designers recognise a number of human characteristics. Second, these observed human features are often seen to coexist or intertwine with each other. Third, these conceptualisations suggest that the relationship between users and designers, as well as the IS-user relation, is a reciprocal process, including characteristics typical of human behaviour.

To begin with, the conception of “the human being reflected in technology” reveals the specific goal of constructing computer interfaces with human-like features: the interaction between people and computers is then envisaged as enriched with dialogues conveying both the rational and emotional meanings of the information in question (e.g., Nakazawa, Mukai, Watanuki & Miyoshi, 2001). Respectively, the depictions of various human features in technology reveal understandings suggesting human features built into technology render the interaction between users and IS as resembling the interplay of cognitive, emotional and social aspects that occur between humans:

R: What kind of user interface do you think that people would want to use?
D4: I strongly believe that 3D interfaces are coming. They could offer kind of human-like facial features as agents, which would bring a human sense to the systems. The third dimension could also be utilised so that interfaces become tangible and accessible.

Further, the context-centred conception of “the human being as an organisational learner,” which highlights people as organisations which learn about their own work processes, refers indirectly to learning, which stresses both cognitive and social human features. Collective cognitive features are referred to as an organisation’s ability to form new insights into its work processes and to guide the deployment of IS effectively (Robey, Boudreau & Rose, 2000). A social dimension is also implied when it is assumed that people learn as an organisation:

D8: Needs are prone to change rapidly, especially after the implementation of the system, because they teach an organisation a lot about itself, and an organisation’s self-knowledge increases and usually needs change in a more clever direction. Then there very quickly happens a sort of ‘learning leap’, which is often experienced as if the system is not valid at all although it is a question
of the organisation’s increased knowledge of its own activity.

Within the conception of “the knowledge sharing human being” the designers open up their view of learning by specifying mutual understanding between users and designers as essential. “It is important to be able to explain things so that we understand each other.” The capability of taking another’s perspectives into account form the core of this conception, which highlights knowledge sharing as a particularly important instance within the processes of organisational learning. Knowledge sharing is the link between individual and group learning, and signifies the expansion of individuals’ cognitive maps into shared understandings (Crossan, Lane & White, 1999). In particular, the ability to take the perspective of others into account is an indispensable prerequisite for knowledge sharing (Boland & Tenkasi, 1995). Buber (1993) ascertains that, in order to be able to take others’ perspectives into account fully, one has to treat others as equal human beings and respect the current circumstances of others. In these kinds of relationships positive emotional features, such as care and joy, need to be acknowledged and combined with cognitive and social abilities (Fredrickson & Branigan, 2001).

Moreover, the conception of “the emotionally coping human being” refers to an ability to regulate in a successful way both negative and positive subjective feelings in computerised situations. In this way, the designers see emotional coping in the light of positive outcomes (cf. Folkman & Moskowitz, 2000, pp.648-649):

D8: ... a skilful user always has such peace of mind and attitude. She or he kind of has a better tolerance for stress, and an ability to cope with contradictions in a better way than others. For some reason this kind of attitude leads to a particular resourcefulness and an ability to utilise the system in a more natural way, compared to a person who has some negative emotional features, fear or hostility towards the system, and who then ends up having difficulties with the system due to her/his heavy attitude.

A cognitive aspect is seen as inherent in emotional coping in that it requires that individuals’ recognise their different emotional experiences. However, in addition to these internal cognitive-affective features, emotion regulation refers to the external social and cultural factors that redirect, control, and shape emotional arousal in such a way that an individual is able to act adaptively in emotionally activating situations (Pulkkinen, 1996). While ISD is often seen as a stressful process which requires an ability to endure changing emotional experiences, such as interest and frustration (Newman & Noble, 1990) in recurrent situations of failure and subsequent success (Robey & Newman, 1996), it is understandable that the designers regard people who are able to regulate their emotions successfully as skilful.

Briefly, the holistic form of thought is comprised of conceptualisations that regard humans as cognitive, emotional, social and cultural creatures. The conceptions belonging to this form of thought embody similar basic human modes of being, as shown above. However, the aforementioned basic modes of being emerge in these conceptions as different behavioural affordances. The cognitive mode of being is seen as intellect, reasoning, learning, reflection, understanding and awareness of something. Similarly, the emotional mode of being is conceptualised as empathy, stress, tranquillity, commitment, contentment and a feeling of mastery. Further, the social mode of being is referred to as a need for communication, group learning, interpersonal power and connection, as well as knowledge sharing. These behavioural affordances are seen as incorporated in technology, appearing between humans, or within the interaction of humans and IS.
THE FORMS OF THOUGHT IN ISD

The IS designers’ forms of thought revealed in the results of this study are regarded as important tools for ISD, and are seen to have implications for the ways that humans are taken into account as users within the different situations of ISD. These different situations refer to the phases of ISD such as planning, design, implementation, use and maintenance. The phases are cyclical and intertwining (e.g., Beynon-Davies, Carne, Mackay, & Tudhope, 1999). Planning refers to initiation and requirements analysis actions, including client contacts and definition of user requirements. During this phase the greatest degree of interaction occurs between users and designers (Newman & Noble, 1990). In order to accomplish requirements analysis, the designers should understand many human issues in addition to technical ones (Holtzblatt & Beyer, 1995). Design denotes procedures where requirements are refined and turned into specifications and finally software. Then technical reliability and maintainability of the system, user interface’s applicability for the intended purpose of the system, as well as the aesthetical appearance of the system, are designed (Smith, 1997). Winograd (1995) emphasises that, in addition to technical requirements, the properties of a user interface should meet with the social, cognitive and aesthetic needs of people. Especially within new ubiquitous technological environments, the design of IS-user relationship should focus, in addition to social and cultural features, on individuals’ perceptual, cognitive and emotional space (Stephanidis, 2001).

How would the designers then perform according to their forms of thought? The strength of the designers utilising a separatist form of thought would be technical knowledge, especially the ability to fluently conceptualise issues of design in accordance with objective definitions, a skill that is needed in creating formal specifications. However, the validity of objectifying design issues is dependent on the focus of such definitions. From a human-centred perspective, valid definitions would require being theoretically sensitive to human activity and deriving second-order conceptions from that activity (see Walsham, 1995), rather than creating objectivist conceptualisations, which overlook humans and their behaviour. An obvious disutility would be a tendency to treat users as technologically ignorant, which implies incompetence in social relationships with users.

The designers embracing the functional form of thought possess technical knowledge, and value such knowledge in users. They tend to focus on formal job descriptions, external work tasks and individuals’ task productivity. A deficit from a human-centred perspective would be the tendency to overlook human issues and to focus instead on the functional purposes of IS; that is, external task information regarding an organizations’ process improvements. Often such conceptualisations are regarded to yield Tayloristic designs, which underestimate the social context. However, they possess competence in functional and technical systems design. Their strength would be increased social competence to fulfil the demand for mutual understanding, which is regarded of utmost importance in ISD (cf. Heng, Traut, & Fischer, 1999).

The designers building upon the holistic form of thought emphasise clients’ satisfaction, which ensures sustainable customer relationships and regard mutual understanding during ISD as essential between users and designers. Their strength would be increased social competence to fulfil the demand for mutual understanding, which is regarded of utmost importance in ISD (e.g., Klein & Hirschheim, 1993; Lyytinen & Ngwenyama, 1992). It seems also likely that they have competence in IS planning which aims at the improvement of organisational processes and are identified as functional, such as sales and purchasing processes, and emphasise mutual understanding. Also, they understand how to maintain customership instead of just visioning economic
Different Levels of Information Systems Designers’ Forms of Thought and Potential

gains or focusing on people’s task productivity. Besides possessing technical competence, these holistic designers would be able to consolidate definitions of formal and external work tasks into human issues. A particularly significant capability would be to understand the process of organisational learning, which is essential in order to adjust the evolving requirements during the process of ISD. Moreover, they value balanced emotional behaviour, and thus intuitively grasp the possible dangers of relying on superfluous emotional behaviour.

With respect to the humanisation of IS, a holistic conception is required in ISD. It is then assumed that the human being is actualised in intertwined physical, cognitive, emotional, social and cultural qualities, and that these qualities are fundamentally different. Without the simultaneous existence of all of the qualities, it is not possible to consider a creature as a human. Yet the qualities cannot be reduced from one quality to another, but rather need to be understood as a whole (Rauhala, 1983). Considering the human being as an actor, as a user of an IS, the whole of a human being is understood as an active subject adjoining to IS. Then the IS-user relationship consists of human action involving explicit and tacit affordances that emerge dynamically in the interaction between humans and IS. In other words, the static characteristics of humans and technology take on a new form within their intertwining activity, which is shaped according to the affordances that, on the one hand, the human substance embodies, and which, on the other hand, the properties of IS support or ignore. Consequently, understanding humans and their behaviour as users of IS requires insight into these emerging human experiences appearing within the affordances and constraints of contemporary IS and their development. Especially at present when the IS are no longer merely tools for personal and professional instrumental productivity, but also (re)constituting and mediating different social structures and practices (e.g., Orlikowski, 1992; Orlowski, 2000), IS acts as social spaces that are important growing social and cultural reference points for users and, thus also for IS designers. Design that takes into account the consequences of the form and functions of IS to users’ social qualities, such as self-identity, is indeed and necessity if contemporary IS development aims at high-quality and usable systems (Greenhill & Isomäki, 2005).

In summary, the resulting forms of thought indicate three different but associated levels of intellectual competence in conceptualising humans as users of IS. The separatist form of thought provides designers predominantly with technical perspectives and a capability for objectifying things. However, it is worth noticing that the validity of objectifying design issues is dependent on the focus of such definitions. From a human-centred perspective, valid definitions would require being theoretically sensitive to human activity and deriving abstracted conceptions from that activity rather than creating objectivist conceptualisations, which overlook humans and their behaviour. The functional form of thought focuses on external task information and task productivity, nevertheless, with the help of positive emotions. The holistic form of thought provides designers with competence of human-centred ISD, even though all the aspects of the richness of the human condition are not revealed. It seems the designers are intellectually more oriented toward designing IS for objectified, streamlined organisational processes consisting of external work tasks, and that this orientation challenges the human-centred orientations.

Chapter 2.15

The Think Aloud Method and User Interface Design

M.W.M. Jaspers

University of Amsterdam, The Netherlands

INTRODUCTION

Daily use of computer systems often has been hampered by poorly designed user interfaces. Since the functionality of a computer system is made available through its user interface, its design has a huge influence on the usability of these systems (Carroll, 2002; Preece, 2002). From the user’s perspective, the user interface is the only visible and, hence, most important part of the computer system; thus, it receives high priority in designing computer systems.

A plea for human-oriented design in which the potentials of computer systems are tuned to the intended user in the context of their utilization has been made (Rossen & Carroll, 2002).

An analysis of the strategies that humans use in performing tasks that are to be computer-supported is a key issue in human-oriented design of user interfaces. Good interface design thus requires a deep understanding of how humans perform a task that finally will be computer-supported. These insights then may be used to design a user interface that directly refers to their information processing activities. A variety of methodologies and techniques can be applied to analyze end users’ information processing activities in the context of a specific task environment among user-centered design methodologies. More specifically, cognitive engineering techniques are promoted to improve computer systems’ usability (Gerhardt-Powels, 1996; Stary & Peschl, 1998).

Cognitive engineering as a field aims at understanding the fundamental principles behind human activities that are relevant in the context of designing a system that supports these activities (Stary & Peschl, 1998). The ultimate goal is to develop end versions of computer systems that support users of these systems to the maximum in performing tasks in such a way that the intended tasks can be accomplished with minimal cognitive effort. Empirical research has indeed shown that cognitively engineered interfaces are considered superior by users in terms of supporting task performance, workload, and satisfaction, compared to non-cognitively engineered interfaces (Gerhardt-Powels, 1996). Methods such as the think aloud method, verbal protocol analysis, or cognitive task analysis are used to analyze in detail the way in which humans perform tasks,
mostly in interaction with a prototype computer system.

**BACKGROUND**

In this section, we describe how the think aloud method can be used to analyze a user’s task behavior in daily life situations or in interaction with a computer system and how these insights may be used to improve the design of computer systems. Thereafter, we will go into the pros and cons of the think aloud method.

**The Think Aloud Method**

Thinking aloud is a method that requires subjects to talk aloud while solving a problem or performing a task (Ericsson & Simon, 1993). This method traditionally had applications in psychological and educational research on cognitive processes. It is based on the idea that one can observe human thought processes that take place in consciousness. Thinking aloud, therefore, may be used to know more about these cognitive processes and to build computer systems on the basis of these insights. Overall, the method consists of (1) collecting think aloud reports in a systematic way and (2) analyzing these reports to gain a deeper understanding of the cognitive processes that take place in tackling a problem. These reports are collected by instructing subjects to solve a problem while thinking aloud; that is, stating directly what they think. The data so gathered are very direct; there is no delay. These verbal utterances are transcribed, resulting in verbal protocols, which require substantial analysis and interpretation to gain deep insight into the way subjects perform tasks (Deffner, 1990).

**The Use of the Think Aloud Method in Computer System Design**

In designing computer systems, the think aloud method can be used in two ways: (1) to analyze users’ task behaviors in (simulated) working practices, after which a computer system is actually built that will support the user in executing similar tasks in future; or (2) to reveal usability problems that a user encounters in interaction with a (prototype) computer system that already supports the user in performing certain tasks.

In both situations, the identification and selection of a representative sample of (potential) end users is crucial. The subject sample should consist of persons who are representative of those end users who will actually use the system in the future. This requires a clearly defined user profile, which describes the range of relevant skills of system users. Computer expertise, roles of subjects in the workplace, and a person’s expertise in the domain of work that the computer system will support are useful dimensions in this respect (Kushnirek & Patel, 2004). A questionnaire may be given either before or after the session to obtain this information. As the think aloud method provides a rich source of data, a small sample of subjects (eight to 10) suffices to gain a thorough understanding of task behavior (Ericsson & Simon, 1993) or to identify the main usability problems with a computer system (Boren & Ramey, 2000). A representative sample of the tasks to be used in the think aloud study is likewise essential. Tasks should be selected that end users are expected to perform while using the (future) computer system. This requirement asks for a careful design of tasks to be used in the study to assure that tasks are realistic and representative of daily life situations. It is recommended that task cases be developed from real-life task examples (Kushnirek & Patel, 2004).

Instructions to the subjects about the task at hand should be given routinely. The instruction on thinking aloud is straightforward. The essence
The Think Aloud Method and User Interface Design

is that the subject performs the task at hand, possibly supported by a computer, and says out loud what comes to mind.

A typical instruction would be, “I will give you a task. Please keep talking out loud while performing the task.” Although most people do not have much difficulty rendering their thoughts, they should be given an opportunity to practice talking aloud while performing an example task. Example tasks should not be too different from the target task. As soon as the subject is working on the task, the role of the instructor is a restrained one. Interference should occur only when the subject stops talking. Then, the instructor should prompt the subject by the following instruction: “Keep on talking” (Ericsson & Simon, 1993).

Full audiotaping and/or videorecording of the subject’s concurrent utterances during task performance and, if relevant, videorecording of the computer screens are required to capture all the verbal data and user/computer interactions in detail. After the session has been recorded, it has to be transcribed. Typing out complete verbal protocols is inevitable to be able to analyze the data in detail (Dix et al., 1998). Videorecordings may be viewed informally, or they may be analyzed formally to understand fully the way the subject performed the task or to detect the type and number of user-computer interaction problems.

The use of computer-supported tools that are able to link the verbal transcriptions to the corresponding video sequences may be considered to facilitate the analysis of the video data (Preece, 2002).

Prior to analyzing the audio and/or video data, it is usually necessary to develop a coding scheme to identify step-by-step how the subject tackled the task and/or to identify specific user/computer interaction problems in detail. Coding schemes may be developed bottom-up or top-down. In a bottom-up procedure, one would use part of the protocols to generate codes by taking every new occurrence of a cognitive subprocess code. For example, one could assign the code guessing to the following verbal statements: “Could it be X?” or “Let’s try X.” The remaining protocols then would be analyzed by using this coding scheme. An excerpt from a coded verbal protocol is given in Figure 1. Note that the verbal protocol is marked up with annotations from the coding scheme. Otherwise, categories in the coding scheme may be developed top-down, for example, from examination of categories of interactions from the human/computer interaction literature (Kushnirek & Patel, 2004). Before it is applied, a coding scheme must be evaluated on its inter-coder reliability.

To prevent experimenter bias, it is best to leave the actual coding of the protocols to a minimum of two independent coders. Correspondence among codes assigned by different coders to the same

The think aloud method and user interface design

Verbal statements must be found, for which the Kappa mostly is used (Altman, 1991).

The coded protocols and/or videos can be compiled and summarized in various ways, depending on the goal of the study. If the goal is to gain a deep insight into the way humans perform a certain task in order to use these insights for developing a computer system to support task performance, then the protocol and video analyses can be used as input for a cognitive task model. Based on this model, a first version of a computer system then may be designed. If the aim is to evaluate the usability of a (prototype) computer system, the results may summarize any type and number of usability problems revealed. If the computer system under study is still under development, these insights then may be used to better the system.

PROS AND CONS OF THE THINK ALOUD METHOD

The think aloud method, preferably used in combination with audio- and/or videorecording, is one of the most useful methods to gain a deep understanding of the way humans perform tasks and of the specific user problems that occur in interaction with a computer system. As opposed to other inquiry techniques, the think aloud method requires little expertise, while it provides detailed insights regarding human task behavior and/or user problems with a computer system (Preece, 2002). On the other hand, the information provided by the subjects is subjective and may be selective. Therefore, a careful selection of the subjects who will participate and the tasks that will be used in the study is crucial. In addition, the usefulness of the think aloud method is highly dependent on the effectiveness of the recording method. For instance, with audiotaping only, it may be difficult to record information that is relevant to identify step-by-step what the subjects were doing while performing a task, whether computer-supported or not (Preece, 2002).

Another factor distinguishing the think aloud method from other inquiry techniques is the promptness of the response it provides. The think aloud method records the subject’s task behavior at the time of performing the task. Other inquiry techniques, such as interviews and questionnaires, rely on the subject’s recollection of events afterwards. Subjects may not be aware of what they actually are doing while performing a task or interacting with a computer, which limits the usefulness of evaluation measures that rely on retrospective self-reports (Boren & Ramey, 2000; Preece, 2002). The advantage of thinking aloud, whether audio- or videotaped, as a data eliciting method includes the fact that the resulting reports provide a detailed account of the whole process of a subject executing a task.

Although using the think aloud method is rather straightforward and requires little expertise, analyzing the verbal protocols can be very time-consuming and requires that studies are well planned in order to avoid wasting time (Dix et al., 1998).

The think aloud method has been criticized, particularly with respect to the validity and completeness of the reports it generates (Boren & Ramey, 2000; Goguen & Linde, 1993).

An argument made against the use of the think aloud method as a tool for system design is that humans do not have access to their own mental processes and, therefore, cannot be asked to report on these. With this notion, verbalizing thoughts is viewed as a cognitive process on its own. Since humans are poor at dividing attention between two different tasks (i.e., performing the task under consideration and verbalizing their thoughts), it is argued that thinking aloud may lead to incomplete reports (Nisbett & Wilson, 1997).

However, this critique seems to bear on some types of tasks that subjects are asked to perform in certain think aloud studies. As Ericsson and Simon (1993) point out, in general, talking out

The Think Aloud Method and User Interface Design

The Think Al oud does not interfere with task performance and, therefore, does not lead to much disturbance of the thought processes. If reasoning takes place in verbal form, then verbalizing thoughts is easy and uses no extra human memory capacity. However, if the information is nonverbal and complicated, verbalization will not only cost time but also extra human memory capacity. Verbalization of thoughts then becomes a cognitive process by itself. This will cause the report of the original task processing to be incomplete, and sometimes, it even may disrupt this process (Ericsson & Simon, 1993). Therefore, the think aloud method only may be used on a restricted set of tasks. Tasks for which the information can be reproduced verbally and for which no information is asked that is not directly used by the subject in performing the task under attention are suitable for introspection by the think aloud method (Boren & Ramey, 2000).

The fact that the experimenter may interrupt the subject during task behavior is considered another source of error, leading to distorted reports (Goguen & Linde, 1993). It has been shown, however, that as long as the experimenter minimizes interventions in the process of verbalizing and merely reminds the subject to keep talking when a subject stops verbalizing his or her thoughts, the ongoing cognitive processes are no more disturbed than by other inspection techniques (Ericsson & Simon, 1993).

The think aloud method, if applied under prescribed conditions and preferably in combination with audio- and/or videorecording, is a valuable information source of human task/behavior and, as such, a useful technique in designing and evaluating computer systems.

**FUTURE TRENDS**

The think aloud method is propagated and far more often used as a method for system usability testing than as a user requirements eliciting method. In evaluating (prototype) computer systems, thinking aloud is used to gain insight into end users’ usability problems in interaction with a system to better the design of these systems. The use of think aloud and video analyses, however, may be helpful not merely in evaluating the usability of (prototype) computer systems but also in analyzing in detail how end users tackle tasks in daily life that in the end will be computer supported. The outcomes of these kinds of analyses may be used to develop a first version of a computer system that directly and fully supports users in performing these kinds of tasks. Such an approach may reduce the time spent in iterative design of the system, as the manner in which potential end users process tasks is taken into account in building the system.

Although a deep understanding of users’ task behaviors in daily settings is indispensable in designing intuitive systems, we should keep in mind that the implementation of computer applications in real-life settings may change and may have unforeseen consequences for work practices. So, besides involving potential user groups in an early phase of system design and in usability testing, it is crucial to gain insight into how these systems may change these work practices to evaluate whether and how these systems are being used. This adds to our understanding of why systems may or may not be adopted into routine practice.

Today, a plea for qualitative studies for studying a variety of human and contextual factors that likewise may influence system appraisal is made in literature (Aarts et al., 2004; Ammenwerth et al., 2003; Berg et al., 1998; Orlikowski, 2000; Patton, 2002). In this context, sociotechnical system design approaches are promoted (Aarts et al., 2004; Berg et al., 1998; Orlikowski, 2000). Sociotechnical system design approaches are concerned not only with human/computer interaction aspects of system design but also take psychological, social, technical, and organizational aspects of system design into consideration. These approaches
take an even broader view of system design and implementation than cognitive engineering approaches—the organization is viewed as a system with people and technology as components within this system. With sociotechnical system design approaches, it can be determined which changes are necessary and beneficial to the system as a whole, and these insights then may be used to decide on the actions to effect these changes (Aarts et al., 2004; Berg et al., 1998). This process of change never stops; even when the implementation of a computer system is formally finished, users will ask for system improvements to fit their particular requirements or interests (Orlikowski, 2000).

**CONCLUSION**

The use of the think aloud method may aid in designing intuitive computer interfaces, because using thinking aloud provides us with a more thorough understanding of work practices than do conventional techniques such as interviews and questionnaires.

Until now, thinking aloud was used mostly to evaluate prototype computer systems. Thinking aloud, however, likewise may be used in an earlier phase of system design, even before a first version of the system is available. It then can be used to elicit every step taken by potential end users to process a task in daily work settings. These insights then may be used as input to the design of a computer system’s first version.

Development, fine-tuning, testing, and final implementation of computer systems take a lot of time and resources. User involvement in the whole life cycle of information systems is crucial, because only when we really try to understand end users’ needs and the way they work, think, and communicate with each other in daily practice can we hope to improve computer systems.

The Think Aloud Method and User Interface Design

KEY TERMS

Cognitive Engineering: A field aiming at understanding the fundamental principles behind human activities that are relevant in context of designing a system that supports these activities.

Cognitive Task Analysis: The study of the way people perform tasks cognitively.

Cognitive Task Model: A model representing the cognitive behavior of people performing a certain task.

Sociotechnical System Design Approach: System design approach that focuses on a sociological understanding of the complex practices in which a computer system is to function.

Think Aloud Method: A method that requires subjects to talk aloud while solving a problem or performing a task.

User Profile: A description of the range of relevant skills of potential end users of a system.

Verbal Protocol: Transcription of the verbal utterances of a test person performing a certain task.

Verbal Protocol Analysis: Systematic analysis of the transcribed verbal utterances to develop a model of the subject’s task behavior that then may be used as input to system design specifications.

Video Analysis: Analysis of videorecordings of the user/computer interactions with the aim to detect usability problems of the computer system.

INTRODUCTION

In recent years, a number of prototypical demonstrators have shown that augmented reality has the potential to improve manual work processes as much as desktop computers and office tools have improved administrative work (Azuma et al., 2001; Ong & Nee, 2004). Yet, it seems that the “classical concept” of augmented reality is not enough (see also http://www.ismar05.org/IAR). Stakeholders in industry and medicine are reluctant to adopt it wholeheartedly due to current limitations of head-mounted display technology and due to the overall dangers involved in overwhelming a user’s view of the real world with virtual information. It is more likely that moderate amounts of augmented reality will be integrated into a more general interaction environment with many displays and devices, involving tangible, immersive, wearable, and hybrid concepts of ubiquitous and wearable computing. We call this emerging paradigm ubiquitous augmented reality (UAR) (MacWilliams, 2005; Sandor, 2005; Sandor & Klinker, 2005).

It is not yet clear which UAR-based human-computer interaction techniques will be most suitable for users to simultaneously work within an environment that combines real and virtual elements. Their success is influenced by a large number of design parameters. The overall design space is vast and difficult to understand.

In Munich, we have worked on a number of applications for manufacturing, medicine, architecture, exterior construction, sports, and enter-
Lessons Learned in Designing Ubiquitous Augmented Reality User Interfaces

tainment (a complete list of projects can be found at http://ar.in.tum.de/Chair/ProjectsOverview). Although many of these projects were designed in the short-term context of one-semester student courses or theses, they provided insight into different aspects of design options, illustrating trade-offs for a number of design parameters. In this chapter, we propose a systematic approach toward identifying, exploring, and selecting design parameters at the example of three of our projects, PAARTI (Echtler et al., 2003), FataMorgana (Klinker et al., 2002), and a monitoring tool (Kulas, Sandor, & Klinker, 2004).

Using a systematic approach of enumerating and exploring a defined space of design options is useful, yet not always feasible. In many cases, the dimensionality of the design space is not known a-priori but rather has to be determined as part of the design process. To cover the variety of aspects involved in finding an acceptable solution for a given application scenario, experts with diverse backgrounds (computer science, sensing and display technologies, human factors, psychology, and the application domain) have to collaborate. Due to the highly immersive nature of UAR-based user interfaces, it is difficult for these experts to evaluate the impact of various design options without trying them. Authoring tools and an interactively configurable framework are needed to help experts quickly set up approximate demonstrators of novel concepts, similar to “back-of-the-envelope” calculations and sketches. We have explored how to provide such first-step support to teams of user interface designers (Sandor, 2005). In this chapter, we report on lessons learned on generating authoring tools and a framework for exploring interaction concepts. Finally, a report on lessons learned from implementing such tools and from discussing them within expert teams of user interface designers is intended to provide an indication of progress made thus far and next steps to be taken.

BACKGROUND

In this section, we provide an overview of the current use of UAR-related interaction techniques and general approaches toward systematizing the exploration of design options.

User Interface Techniques for Ubiquitous Augmented Reality

User interfaces in UAR are inspired by related fields, such as virtual reality (VR) (Bowman, Kruijff, LaViola, & Poupyrev, 2004), attentive user interfaces (AUIs) (Vertegaal, 2003), and tangible user interfaces (TUIs) (Ishii & Ullmer, 1997). Several interaction techniques for VR have been adapted to UAR: for example the World-in-Miniature (Bell, Höllerer, & Feiner, 2002), pinch gloves for system control (Piekarski, 2002), and a flexible pointer to grasp virtual objects that are beyond arm’s reach (Olwal & Feiner, 2003). The core idea of TUIs is to use everyday items as input and output simultaneously. This idea has also been applied to UAR: for example the World-in-Miniature (Bell, Höllerer, & Feiner, 2002), pinch gloves for system control (Piekarski, 2002), and a flexible pointer to grasp virtual objects that are beyond arm’s reach (Olwal & Feiner, 2003).
Implementing New Interaction Techniques

To develop new interaction techniques and visualizations for UAR, several software infrastructures have been created to simplify the development of new interaction techniques by programmers: distributed frameworks, dataflow architectures, user interface management systems, scene graph-based frameworks, a variety of class libraries, and finally scripting languages. A detailed discussion can be found in Sandor (2005).

For novice users, several desktop tools for authoring augmented reality content have been developed: PowerSpace (Haringer & Regenbrecht, 2002), DART (MacIntyre, Gandy, Dow, & Bolter, 2004), and MARS (Güven & Feiner, 2003). Several systems exist that follow an immersive authoring approach (Lee, Nelles, Billinghurst, & Kim, 2004; Poupyrev et al., 2001). Piekarski describes a mobile augmented reality system that can be used to capture the geometries of real objects (Piekarski, 2002). Several hybrid authoring approaches combine immersive authoring with desktop authoring (Olwal & Feiner, 2004; Zauner, Haller, Brandl, & Hartmann, 2003).

DESIGN OPTIMIZATION FOR HIGH-DIMENSIONAL DESIGN SPACES

One of the most difficult issues in designing novel interaction techniques for UAR is the wealth of criteria that are potentially involved in finding an optimal solution. We divide such criteria into three classes: criteria pertaining to the task(s) that need to be executed, the knowledge and skills of the user, and the current state-of-the-art of technology. Figure 1 illustrates the classes and their relationships.

Classes of Design Criteria

- **Task-specific criteria** are related to the requirements of specified tasks in an application. According to principles of software engineering, they are determined from scenarios and use cases, taking the environmental setting and the required technical quality into account. Yet, they may change over time due to changing work processes, which may indirectly depend on evolving technology.

- **System-specific criteria** are defined by the state-of-the-art of engineering-related parameters of sensing and display devices and computer systems. Due to evolving technology, these criteria have to be continuously re-evaluated, resulting in ever-changing optimal system configurations (Klinker et al., 1999).

- **User-specific criteria** depend on ergonomic issues and the cultural background of users—human factors and anthropology. They describe current working conditions, habits (working culture), and educational background, as well as specific user-related restrictions.
Criteria Reduction through Inter-Class Constraints

Finding an overall optimal system that works perfectly with respect to all criteria seems to be impossible. We have thus adopted the approach of selecting specific criteria of one or two classes to impose constraints on design options in other classes. In this section, we analyze the relationship between the classes of criteria from user-, system-, and task-centric specifications. Later we illustrate the exploitation of such constraints in specific examples.

The relationships between task and system requirements are described by the edge linking the task and system nodes in Figure 1. From the task-perspective, they are described as the functional and non-functional requirements of software systems. From the system-perspective, they need to be matched with the currently available technical options. Trade-offs must be made to obtain pragmatically implementable solutions—with an eye toward upcoming requirements and technical developments. Later, we will present an example of casting such trade-offs.

The relationships between task and user requirements are described by the edge linking the task and user nodes in Figure 1. This case does not involve any considerations of currently available technology. Thus, options that are discussed here should hold true now, as well as 100 years ago or 100 years in the future. They are analyzed by disciplines such as task analysis and system ergonomics (Bubb, 1993). Yet, they can provide significant constraints upon today’s technically achievable system configurations. We will present an example of analyzing how a user (car designer) physically behaves with respect to a number of tasks geared toward analyzing and comparing different automotive designs.

The relationships between system and user are described by the edge linking the system and user nodes in Figure 1. From the user-perspective, they are described as usability criteria, evaluating how users perform, given a specific technical system—in comparison to other technical options. From the system-perspective, they describe user requirements that need to be satisfied with currently available technical means. Later, we show an example of how a specific technical device can be evaluated with respect to specific physical user skills in using such a device.

Dealing with Ill-Defined Design Spaces

By applying inter-class constraints on a user interface, the design space can often be reduced considerably. The next step in our proposed design process is to explore the reduced design space with interactive tools that encourage collaboration. In this section, we first give the rationale for our interactive tools. Then, we proceed by highlighting the problems that occur when using this approach. Finally, we give an outlook of how we elaborate on these concepts within this chapter.

To further explore the design space, collaboration between researchers with different backgrounds is imperative to yield a solution that is well balanced according to our three main classes: user, task, and system. Thinking about this problem led to the invention of a new development process: Jam Sessions. The name Jam Sessions was inspired by the spontaneous collaboration of Jazz musicians that is also named Jam Sessions. However, in our case we collaborate on user interface elements, instead of music. In Jam Sessions, development takes place at system runtime, next to a running system. This allows playful exploration of user interface ideas. Our experience with Jam Sessions was first presented in (MacWilliams et al., 2003); we have already discussed these from a software engineering (MacWilliams, 2005) and user interface (Sandor, 2005) perspective.

To support this development process, interactive tools for novices are an important ingredient, since they foster the interdisciplinary collabora-
Lessons Learned in Designing Ubiquitous Augmented Reality User Interfaces

...tion with other researchers. Desirable would be a set of generic tools that can be applied in all Jam Sessions—independent of the user interface to be developed. Although we have achieved this for programmers, for novices this is yet an unsolved problem. We go in line with several other research tools that allow modifying only a quite limited amount of user interface functionality. Since these tools are customized toward the user interface that has to be built, most projects require writing new tools. Thus, a sophisticated software infrastructure that quickly allows building new tools is very useful.

The final section of this chapter describes a complex user interface that we have designed in Jam Sessions. Additionally, we first describe briefly our software infrastructure and elaborate on the tools that we have created for this project.

PROJECTS USING INTER-CLASS CONSTRAINTS

This section presents three examples of analyzing design options by exploring inter-class constraints.

PAARTI

In the PAARTI project (practical applications of augmented reality in technical integration), we have developed an intelligent welding gun with BMW that is now being used on a regular basis to weld studs in the prototype production of cars (Echtler et al., 2003). It exemplifies the systematic exploitation of constraints between task and system criteria.

The task was to assist welders in positioning the tip of a welding gun with very high precision at some hundred predefined welding locations on a car body. The main system design issue was to find an immersive solution with maximal precision. An AR-based system would need a display (D), a tracking sensor (S), and some markers (M) that needed to be installed in the environment on the user or on the welding gun in a manner that would yield maximal precision. As a fourth option, we considered the case that one of the objects (esp.: markers) would not be necessary at all. The result was the definition of a 3-dimensional design space, $S \times M \times D$, with each dimension spanning a range of four options. In total, there were $4^3 = 64$ solutions that needed to be considered.

According to an analysis of all options, the highest precision could be achieved by using an outside-in tracking arrangement with sensors placed in the welding environment and markers attached to the welding gun. A small display was attached to the welding gun. The visualization used a notch and bead metaphor of real guns, consisting of several concentric rings. A sphere was positioned three-dimensionally at the next welding location. Welders were requested to capture the sphere within the concentric rings by moving the gun (and the display) to the appropriate location (see Figure 2(a)).

The left diagram of Figure 2(b) shows the optimal setup. The center diagram of Figure 2(b) indicates the design space of $S \times M = 16$ options of placing markers and sensors in the environment, with the fixed display dimension D of placing the display on the welding gun. The right diagram presents the analysis pertaining to the achievable precision for this setup. This setup clearly outperforms the classical AR-arrangement involving a head-mounted display (Echtler et al., 2003).

FataMorgana

In the FataMorgana project, we have developed an AR-based prototypical demonstrator for designers at BMW, helping them compare real mock-ups of new car designs with virtual models (Klinker et al., 2002). The rationale for building this system was that, although the importance of digital car models is increasing, designers have not yet committed wholeheartedly to a VR-based approach but rather prefer relying on physical
mock-ups. One of the reasons may be that special viewing arrangements such as projection walls do not permit people to view the digital models within a real environment. AR can help alleviate this problem by placing virtual cars next to real (mock-up) cars.

Here we present this project as an example of a systematic analysis of the relationships between tasks and user actions. The underlying thesis is that users (designers) behave in specific ways in order to achieve tasks. If a system is expected to support users in achieving their tasks, it has to be designed to function well within the range of typical actions performed by the user. To this end, we have subdivided the task in a set of different approaches and asked a designer to act out each of these tasks within the real car presentation environment. We recorded the designer’s motions with a camera that was attached to his head (Figure 3).
Lessons Learned in Designing Ubiquitous Augmented Reality User Interfaces

Figure 3. Five different tasks resulting in different user head motions (© 2002 IEEE, Klinker et al., 2002)

- **Turning**: The car designer remains in a fixed location and looks at the car rotating on a turn table.
- **Overview**: The car designer performs an overview evaluation of the car, by walking around and turning his head to change the lighting conditions.
- **Detail**: The car designer focuses on a specific detail of the car, such as a character line on the side of the car or the shape of the front spoiler.
- **Discuss**: The car designer discusses the car under evaluation with a colleague.
- **Compare**: The car designer compares two cars, for example, an existing car and a new design.

For each scenario, we determined the typical angular range of head rotations, as well as the range of positional changes. Combined with a projection of the field of view onto the environment, this gave us an indication how markers had to be laid out in the room in order to guarantee that enough of them were clearly visible during all user actions.

**Monitoring Tool for Determining Usage Patterns of Novel Interaction Techniques**

We have developed a monitoring tool (Kulas et al., 2004) to evaluate the usability of novel input techniques and devices. The monitoring tool allows us to systematically analyze relationships between user and system criteria, analyzing whether a system is well tailored to the physiological and cognitive skills of its users.

We have used the monitoring tool to evaluate the usability of a novel input device called TouchGlove that was developed at Columbia University (Blasko & Feiner, 2002). It consists of a touch-sensitive plate (similar to a touchpad in a laptop) that is attached to the center of a user’s palm. It is sensitive to single-finger input, measuring 2D location and pressure. In the evaluation setup, we have compared two techniques of using
Lessons Learned in Designing Ubiquitous Augmented Reality User Interfaces

the TouchGlove to select items from a menu. In the first case, users were asked to make a linear gesture with their fingertip on the TouchGlove to select items from a regular pull-down menu. In the second case, the TouchGlove was combined with a gyroscope to select items from a pie menu. Users were asked to rotate their hands around their wrists, generating only a tapping signal on the touchpad to signal start and end of the gesture rotating the pie menu.

During a usability evaluation, the user is placed at a suitable distance from a usability engineer. The engineer enters observations into a usability logging system and also monitors what the user actually sees on screen. Simultaneously, he also monitors real-time visualizations of measured usability data. The tool provides immediate feedback during an interactive tryout session, thereby supporting Jam Sessions.

INTERACTIVE TOOLS FOR COLLABORATIVE DESIGN SPACE EXPLORATIONS

This section presents our tools for supporting Jam Sessions. First, we give a brief overview of our tools. Second, we present an interdisciplinary research project, CAR, which uses them. We close with a description of the underlying real-time development environment.

Overview of Tools

To support Jam Sessions, we have created a toolbox of lightweight and flexible tools. They form the basic building blocks which user interface development teams can use to generate, experience, and test their novel interaction techniques.

The tools use AR, TUI, and WIMP interaction paradigms and are designed to support a number of tasks. The first task focuses on monitoring the user. The second task involves the configuration of dataflow networks. UAR systems need to communicate in real-time with many sensing and display devices, requiring a distributed system approach. A dataflow network connects such devices and components. We provide tools that allow modifying these dataflow graphs during runtime. Another task is related to the adjustment of dialog control, i.e., the control of the high-level behaviour of a user interface. Tools that enable developers to specify dialog control quickly speed up the development process significantly. The final task involves the creation of context-aware animations. Conventional animations have time as the only parameter that changes the appearance of graphical elements. However, for mobile systems a variety of research projects (e.g., a context-aware World-in-Miniature [Bell et al., 2002]) have explored animations that change their appearance according to context.

We have developed six tools, T1–T6, in support of these tasks. T1 collects and evaluates usability data during system runtime. T2 uses an augmented reality visualization to shows a user’s visual focus of attention in a combination of head and eye tracking (Novak et al., 2004) (see Figure 9). T3 is a graphical editor, DIVE to adjust dataflow networks (MacWilliams et al., 2003; Pustka, 2003) (see Figure 10[a]). T4 is an immersive visual programming environment (Sandor, Olwal, Bell, & Feiner, 2005). T5 is a User Interface Controller Editor, UIC, to graphically specify dialog control by composing Petri nets (Hilliges, Sandor, & Klinker, 2004) (see Figure 10[b)). T6 is a collection of tools to experiment with context-aware mobile augmented reality user interfaces.

Figure 4 classifies our tools with respect to the user interface paradigms they employ and the tasks they address (Sandor, 2005). It shows that we sometimes developed several tools, addressing the same task, using different interaction paradigms. This reflects our goal of exploring and comparing design options for our own tools as much as for the interaction techniques that will be developed with them.
Lessons Learned in Designing Ubiquitous Augmented Reality User Interfaces

CAR

CAR is an industry-sponsored multi-disciplinary project to investigate issues pertaining to the design of augmented reality user interfaces in cars. CAR has used most of the tools T1-T6 to investigate several user interface questions.

Motivation

In CAR, we have investigated a variety of questions: How can information be presented efficiently across several displays that can be found in a modern car (e.g., the dashboard, the board computer, and heads-up displays (HUDs))? How can we prevent that information displayed in a HUD is blocking the driver’s view in crucial situations? Since a wealth of input modalities can be used by a car driver (tactile, speech, head and hand gestures, eye motion), which modalities should be used for which tasks?

In a multi-disciplinary UI design team, we have discussed, for example, how to present a navigation map on a HUD. Where should it be placed? How large should it be? What level of detail should it provide? Should it be a two-dimensional map or a tilted view onto a three-dimensional environmental model (WIM)? If so, which viewing angle should be selected? Will the angle, as well as the position of the WIM and the size and zoom factor adapt to sensor parameters, such as the current position of the car while approaching a critical traffic area in a town?
Physical Setup

We have set up a simulator for studying car navigation metaphors in traffic scenes (Figure 5). It consists of two separate areas: a simulation control area (large table with a tracked toy car) and a simulation experience area (person sitting at the small table with a movable computer monitor in the front and a stationary large projection screen in the back). In the simulation control area, members of the design team can move one or more toy cars on the city map to simulate traffic situations, thereby controlling a traffic simulator via a tangible object. The simulation experience area represents the cockpit of a car and the driver. The picture projected on the large screen in the front displays the view a driver would have when sitting in the toy car. The monitor in front of the driver provides a mock-up for the visualizations to be displayed in a HUD. Further monitors can be added at run-time, if more than one view is needed.

The room is equipped with an outside-in optical tracking system (http://www.ar-tracking.de). The cameras track the toy car, the computer monitor, and the user (simulating a car driver). Each tracked object is equipped with a marker consisting of a rigid, three-dimensional arrangement of reflective spheres.

Information is presented on several devices and surfaces in the room: A projector at the ceiling projects a bird’s eye view of a city onto the large, stationary table on the right. Another projector presents the current, egocentric view of a virtual car driver sitting in the toy car on the large screen at the front wall. A third, location-dependent visualization of the driving scenario is shown on the mobile computer monitor—our substitute for a HUD.

The system provides tools for a team of design experts with diverse backgrounds to jointly explore various options to present a map (Figure 6).
Lessons Learned in Designing Ubiquitous Augmented Reality User Interfaces

Controlling the Context-Aware Adjustment of a Navigation Map

It is not yet clear how navigational aids are best presented within a driver’s field of view. In the CAR project, we have experimented with various options of placing and orienting a map in a HUD.

Figure 7 shows how our system provides designers with a tangible object—a plate—that is correlated with the orientation (tilt) and zoom of a 3D map on the HUD. When the user moves the tangible plane, the 3D map is turned and zoomed accordingly on the HUD. Figure 6(a) shows a member of the design team experiment with different map orientations.

The position and size of a map in a HUD may have to depend on various parameters that depend on the driving context, such as the current position of the car relative to its destination, the driver’s viewing direction, and immanent dangers in the environment. Interface designers need to explore schemes for the display system to automatically adapt to context parameters. Figure 8 shows an interactive sketching tool for designers to describe functional dependencies between context parameters and display options. Figure 9 shows first steps toward using tracked head and eye motions to provide a context-dependent interaction scheme (Novak et al., 2004). Figure 6(a) shows the head and eye tracking device. We are in the process of analyzing context-dependent information presentation further. First user studies of selected issues are presented in Tönnis, Sandor, Klinker, Lange, and Bubb (2005).

Real-Time Development Environment for Interaction Design

The tools presented in earlier sections were geared toward the immediate use by non-programming user interface experts. They mainly address the customization of a set of functionalities and filters, linking context measurements to information presentation schemes. In order to add new functionality to a system, the development team must also be able to modify the underlying network of components, and its dataflow scheme. Tools T3 and T5 provide such support.

All system configuration tools are based on DWARF (distributed wearable augmented reality framework) (Bauer et al., 2001) and AVANT-

Figure 9. Attentive user interface, visualizing a driver’s eye and head motions: (a) The DWARF’s Interface Visualization Environment for managing distributed components; (b) The User Interface Controller for specifying dialog control

GUADE (Sandor, 2005; Sandor & Klinker, 2005). DWARF is the underlying infrastructure that connects a set of distributed components. AVANTGUADE is composed of DWARF components that address the specific requirements for user interfaces in UAR.

DWARF’s interactive visualization environment (MacWilliams et al., 2003) (tool T3, Figure 10[a]) enables developers to monitor and modify the dataflow network of distributed components. However, since this requires substantial knowl-
Lessons Learned in Designing Ubiquitous Augmented Reality User Interfaces

The core component of AVANTGUARDE is a Petri net-based dialog control management system (Hilliges et al., 2004) (Tool T5, Figure 10[b]). We have developed a visual programming environment that eases the modification of the Petri nets (and accordingly the user interface) during system runtime. However, it is still too difficult to use for non-programming design experts, since understanding Petri nets requires knowledge in computer science.

CONCLUSION

In PAARTI and FataMorgana, we have learned that the reduction of criteria through inter-class constraints is a valuable approach for designing user interfaces. The crucial issue of this method is to determine the most important constraints by talking with domain experts. The subsequent systematic design space exploration is straightforward.

We have presented an example for the inter-class constraint of user and system: the evaluation of the TouchGlove input device. In this project, we have observed the importance of immediate feedback through interactive tools. Our first prototype of the TouchGlove had a loose contact. While we conducted the usability study with the first user, we immediately spotted the problem and solved it. This saved us a lot of valuable time.

Our tool-based approach for further design space explorations has been applied successfully in several projects. The idea of providing user interface developers with a toolbox of flexible, lightweight tools seems feasible. However, one
problem has to be pointed out: when creating a variety of tools, a supporting real-time development environment is imperative. Otherwise, too much development time has to be allocated to tool creation—leaving little time for the actual use of the tools. In this respect, we have successfully built our tools on top of DWARF and AVANTGUARDE.

The combination of tools with different user interface paradigms turned out to be a valuable idea. We have made two important observations: first, there seems to be a trade-off between ease of use for a tool and the complexity of results that can be accomplished with it. WIMP tools can be used to model more complex interactions, whereas ease of use is greater with tools that have a tangible user interface or an augmented reality user interface. Second, the combination of tools with different paradigms opens new possibilities of interaction design that would not be possible with tools employing a single paradigm. Interaction designers are typically not fluent in complex programming tasks, so their involvement with easy to use tools yields important benefits.

Ideally, it would be enough to create one generic tool that novices can use to explore the design space of UAR user interfaces. Our first prototype toward this goal has been published in Sandor et al. (2005).

This tool seems to be very easy to use, as it employs only direct manipulation of real world objects—no conventional programming is required at all. However, the ceiling of the tool (i.e., what can be achieved with it) is quite low, since our system supports only a fixed, and very limited number of operations. We are exploring how we can extend it to allow users to specify new operations at runtime. While we anticipate using programming-by-demonstration to address a carefully planned universe of possibilities, supporting arbitrary operations through demonstration and generalization is an open problem.

The CAR project also showed us that for design space explorations, rapid prototyping is more important than realism for finding new interaction techniques. Though, for the thorough evaluation of these new concepts, formal usability studies within a realistic environment are still necessary. We have conducted a first study in this respect (Tönnis et al., 2005).

Chapter 2.17
Social Network Structures in Open Source Software Development Teams

Yuan Long
Colorado State University-Pueblo, USA

Keng Siau
University of Nebraska-Lincoln, USA

ABSTRACT
Drawing on social network theories and previous studies, this research examines the dynamics of social network structures in open source software (OSS) teams. Three projects were selected from SourceForge.net in terms of their similarities as well as their differences. Monthly data were extracted from the bug tracking systems in order to achieve a longitudinal view of the interaction pattern of each project. Social network analysis was used to generate the indices of social structure. The finding suggests that the interaction pattern of OSS projects evolves from a single hub at the beginning to a core/periphery model as the projects move forward.

INTRODUCTION
The information system development arena has seen many revolutions and evolutions. We have witnessed the movement from structured development to object-oriented (OO) development. Modeling methods, such as data flow diagram and entity relationship diagram, are facing new OO modeling languages, such as the unified modeling language (UML) (see Siau & Cao, 2001; Siau, Erickson, & Lee, 2005; Siau & Loo, 2006) and OO methodologies, such as unified process (UP). The latest development includes agile modeling (see Erickson, Lyytinen, & Siau, 2005), extreme programming, and OSS development. While many of these changes are related to systems development paradigms, methodologies, methods, and techniques, the phenomenon of OSS development entails a different structure for software development teams.
Unlike conventional software projects, the participants of OSS projects are volunteers. They are self-selected based on their interests and capability to contribute to the projects (Raymond, 2000). In addition, the developers of OSS projects are distributed all around the world. They communicate and collaborate with each other through the Internet, using e-mails or discussion boards. Therefore, effective and efficient communication and collaboration are critical to OSS success. However, little empirical research has been conducted to study the underlying interaction pattern of OSS teams, especially the dynamics of the social network structures in OSS development teams. To fill this gap, this study examines the evolvement of social structure in OSS teams. The study contributes to the enhancement of the understanding of OSS development, and provides foundation for future studies to analyze the antecedents and consequences of social networks in the OSS context.

The remainder of the paper is structured as follows. First, prior studies on social network structures in OSS teams are reviewed. Second, theories related to social structure and social network theory are discussed. Third, the research methodology is presented, and the research results are reported. Next, discussions of the results, the limitations, and the implications are provided. The paper concludes with suggestions for future research.

LITERATURE REVIEW

The phenomenon of OSS development has attracted considerable attention from both practitioners and researchers in diverse fields, such as computer science, social psychology, organization, and management. Because of the multifaceted nature of OSS, researchers have investigated OSS phenomenon from varied perspectives. For example, focusing on technical perspective, researchers studied issues such as OSS development methodology (e.g., Jørgensen, 2001) and coding quality (e.g., Stamelos, Angelis, Oikonomu, & Bleris, 2002). Based on social psychology, researchers investigated individual motivation (e.g., Hann, Robert, & Slaughter, 2004), new developers (Von Krogh, Spaeth, & Lakhani, 2003), the social network (e.g., Madey, Freeh, & Tynan, 2002), and the social structure (e.g., Crowston & Howison, 2005). In terms of organizational and managerial perspective, researchers examined knowledge innovation (e.g., Hemetsberger, 2004; Lee & Cole, 2003, Von Hippel & Von Krogh, 2003) and the governance mechanism (e.g., Sagers, 2004).

An OSS development team is essentially a virtual organization in which participants interact and collaborate with each other through the Internet. Compared to conventional organizations, the structure of virtual organizations is decentralized, flat, and nonhierarchical (Ahuja & Carley, 1999). However, some researchers challenge the belief (e.g., Crowston & Howison, 2005; Gacek & Arief, 2004; Mockus, Fielding, & Herbsleb, 2000; Mockus, Fielding, & Herbsleb, 2002; Moon & Sproull, 2000). They argue that the social structure of OSS projects is hierarchical rather than flat, like a tree (Gacek & Arief, 2004) or an onion (Crowston & Howison, 2005). The social structure of OSS teams directly influences the collaboration and the decision-making process and further affects the overall performance of the teams as well as individuals’ perception of belonging and satisfaction. Therefore, one wonders what form of social structure might be present in the OSS development and what type of structure will emerge—centralized or decentralized, hierarchical or nonhierarchical, onion-like or tree-like, or a combination of the above depending on certain specific situations?

A social network, as stated by Krebs and Holley (2004), is generally built in four phases, each with its own distinct topology (as shown in Figure 1).
1. scattered clusters,
2. single hub-and-spoke,
3. multihub small-world network, and
4. core/periphery.

Most organizations start from isolated and distributed clusters (Krebs & Holley, 2004). Then an active leader emerges and takes responsibility for building a network that will connect the separate clusters. However, this single-hub topology is fragile. With more participants entering the group, the leader changes his/her role to a facilitator and helps to build multiple hubs, which is stage three. The core/periphery model, the last stage, is the most stable structure. In the core/periphery model, the network core encompasses key group members who are strongly connected to each other, while the periphery contains members who are usually weakly connected to each other as well as to the core members. With the general network building phases in mind, one can argue that OSS projects may follow the same four stages (i.e., scattered clusters, single hub-and-spoke, multihub small-world network, and core/periphery model). But is that true for OSS projects? How does the social structure of OSS teams evolve over time?

Our research addresses the following two questions:

1. What is the social structure of OSS teams?
2. How does the social structure evolve over time?
THEORETICAL FOUNDATION

Social Structure and Social Interaction

Social structure, as suggested by Schaefer and Lamm (1998), refers to the way in which society is organized into predictable relationships. Social structure can be considered in terms of three aspects—actors, their actions, and their interactions. The social actor is a relatively static concept addressing issues such as roles, positions, and statuses. Individual actors are embedded in the social environment and, therefore, their actions are largely influenced by the connections between each other. Social interaction is generally regarded as the way in which people respond to one another. These interaction patterns are to some extent independent of individuals. They exert a force that shapes both behavior (i.e., actions) and identity (i.e., actors) (Schaefer & Lamm, 1998).

Research on social interaction focuses on how individuals actually communicate with each other in group settings. These studies address issues such as the interaction patterns, the underlying rules guiding interaction, the reasons accounting for the way people interact, and the impacts of the interaction patterns on the individual behavior and the group performance. These issues begin by questioning what might be the interaction pattern in a specific social setting and that addresses our research question—understanding social interaction of OSS project teams.

Social Network Theory

Social network theory focuses on studying actors as well as their relationships in specific social settings. Network theory is analogous to systems theory and complexity theory. It is an interdisciplinary theory stemming from multiple traditional fields, including psychology, which addresses individuals’ perception of social structure; anthropology, which emphasizes social relationships; and mathematics, which provides algorithms (Scott, 2000).

Based on the view of social network, the world is composed of actors (also called nodes) and ties between them. The ties can represent either a specific relationship (such as friendship and kinship) between a pair of actors or define a particular action which an actor performs. Different kinds of ties specify different networks and are typically assumed to function differently. For example, the ties in a family network are distinctive from those in a working network, and the centrality in the “who loves whom” network obviously has different meaning than the centrality in the “who hates whom” network.

Social network theory is based on the intuitive notion that the social interaction patterns are essential to the individuals who reflect them. Network theorists believe that how individuals behave largely depends on how they interact with others and how they are tied to a social network. Furthermore, besides individual behavior, network theorists believe that the success or failure of societies and organizations often depends on the internal interaction pattern (Freeman, 2004).

Besides the theoretical essence, social network theory is also characterized as a distinctive methodology encompassing techniques for data collection, statistical analysis, and visual representation. This approach is usually called social network analysis and will be discussed in the research methodology section. This paper draws on the social network theory to study the interaction pattern of OSS development project.

RESEARCH METHODOLOGY

Social Network Analysis

Social network analysis is used in our study to investigate the interaction pattern of the OSS development process. Social network analysis
focuses on uncovering the interaction pattern of interdependent individuals (Freeman, 2004). Through a structural analysis of a social network diagram, a map depicting actors as well as the ties that connect them, social network analysis can reveal the patterns of relationships and the relative position of individuals in a specific social setting. This approach has been effectively used in organizational research, social support, mental health, and the diffusion of information (Freeman, 2004).

Social network analysis is used in our study for two primary reasons. First, the purpose of social network analysis fits our research objective. Social network analysis aims to analyze the relationship among a set of actors instead of their internal attributes. Our research aims to reveal the interaction pattern of OSS project teams. Therefore, social network analysis is helpful in answering our research questions.

Second, the rich interactive data extracted from OSS projects presents a “gold mine” for social network analysis. Social network analysis is grounded in the systematic analysis of empirical data. However, there is usually a lack of convenient and objective resources from which to draw the links (i.e., relationships) among actors. Most OSS projects have online mailing lists, forums, and tracking systems that are open to public, thus providing a rich set of longitudinal data. Based on these public data, researchers are able to capture input data sets for social network analysis.

**Longitudinal Data**

Because we are interested in studying how the interaction pattern of OSS projects evolves over time, cross-sectional observations of interaction networks are not sufficient. Cross-sectional observations of social networks are snapshots of interactions at a point in time and cannot provide traceable history, thus limiting the usefulness of the results. On the other hand, longitudinal observations offer more promise for understanding the social network structure and its evolvement. In this study, we extracted longitudinal data on OSS projects.

**Case Selection**

OSS projects were selected from the SourceForge\(^1\), which is the world’s largest Web site hosting OSS projects. SourceForge provides free tools and services to facilitate OSS development. At the time of the study, it hosted a total of 99,730 OSS projects and involved 1,066,589 registered users (This data was retrieved on May 4, 2005). Although a few big OSS projects have their own Web sites (such as Linux), SourceForge serves as the most popular data resource for OSS researchers.

Following the idea of theoretical sampling (Glaser & Strauss, 1967), three OSS projects were selected from SourceForge in terms of their similarities and differences. Theoretical sampling requires theoretical relevance and purposes (Orlikowski, 1993). In terms of relevance, the selection ensures that the interaction pattern of OSS projects over time is kept similar. Therefore, the projects that are selected have to satisfy two requirements. First, the projects must have considerable interaction among members during the development process. All three projects had more than 10 developers, and the number of bugs reported was more than 1,000. Second, since we are interested in the interaction over time, the projects must have a relatively long life. In our case, all three projects were at least three years old.

In addition to similarities, differences are sought among cases because the study aims to study interaction patterns of various OSS projects. Therefore, the three projects differ on several project characteristics, such as project size, project type, and intended audience. These differences enable us to make useful contrasts during data analysis.

The Table 1 summarizes the three projects with a brief description.
Data Collection and Analysis

Social network analysis can be divided into the following three stages (Borgatti, 2002).

1. Data collection. In this stage, researchers collect data, using surveys and questionnaires, or from documents and other data resources, and generate input data sets for social network analysis.

2. Statistical analysis. Based on mathematics algorithms, this stage generates network indices concerning group structure (such as centralization and density) as well as individual cohesion (such as centrality and bridges).

3. Visual representation. This stage employs network diagrams to show the interaction structure as well as the position of specific actors.

First is the data collection. The data were collected in April 2005 from SourceForge.net. Data were extracted from the bug tracking system of each project. We chose the bug tracking system as the primary data resource for three reasons. First, open source software is characterized as peer review of open codes. Raymond (1998) proposed the “Linus’ law” in his well-known essay *The Cathedral and the Bazaar*— “Given enough eyeballs, all bugs are shallow.” Therefore, the bug system can be viewed as the representative of open source spirit. Second, compared to other development activities, such as patch posting and feature request, the bug-fixing process is the most active procedure to illustrate the close

Social Network Structures in Open Source Software Development Teams

A Web spider program, which is based on the work of Crowston and Howison (2005) with necessary revision, was used to download the bug tracking Web pages from the project Web site. After that, a Web parsing program was developed to analyze the Web pages. The interaction data was extracted from the bug tracking Web pages month-by-month, starting from the date the project was registered until the date the data was downloaded for this study. The output of this stage is a social matrix describing the interaction among users. Figure 2 shows an example of such a social matrix for an OSS project. In the matrix, each row or column represents a distinctive participant, which is identified by a unique SourceForge user identity. The values of cells indicate the degree of the interaction between each pair of participants, which is counted by the amounts of messages that participant A (i.e., row A) replied to participant B (i.e., column B).

Second is the statistical analysis. Our study focuses on two important and distinctive properties of network structure—group centralization and core/periphery fitness. Ucinet, which was developed by Borgatti, Everett, and Freeman (2002), was used to calculate these two properties.

Group centralization, as suggested by Wasserman and Faust (1994), refers to the extent to which a network revolves around a single center. A typical case of centralized structure is a “star” network. Group centralization can be viewed as a rough measure of inequity between individual actors, and the variability and dispersion of the interaction pattern.

The other property is core/periphery fitness. It measures the extent to which the network is close to a perfect core/periphery structure. The core/periphery structure depicts a dense, connected group
surrounded by a sparse, unconnected periphery. The opposite structure is clique, which represents a structure of multiple subgroups, each with its own core and peripheries (Borgatti, 2002).

Finally is the visual representation. We used Ucinet (Borgatti et al., 2002) to draw the interaction networks for each of the three projects.

**RESEARCH RESULTS**

**Snapshots of the Three Projects**

Monthly data were extracted from the bug tracking system of each project. To illustrate the trend of interaction pattern, we provide three snapshots for each project (see Figures 3-5)

Table 2 summarizes the relevant network characteristics of each project. In addition to the group centralization and core/periphery fitness, we also report other network characteristics, such as density, average distance, and distance-based cohesion. Density depicts how “close” the network looks, and it is a recommended measure of group cohesion (Blau, 1977; Wasserman & Faust 1994). The value of density ranges from 0 to 1. Average distance refers to average distance between all pairs of nodes (Borgatti, 2002). Distance-based cohesion takes on values between 0 and 1—the larger the values, the greater the cohesiveness.

Looking at the statistical results and the network plots, we can observe the following.

First, the evolvement of interaction patterns of the three projects reveals a general trend. As shown in the network plots (i.e., Figures 3-5), the interaction pattern develops from a centralized one with a single (sometimes dual) hub with several distributed nodes, to a core/periphery
structure that has a core (a group of core developers) together with several hangers-on (periphery). Intense interactions exist within the core (among several core developers) and between each core member and his/her periphery. However, only loose relationships exist among peripheries. This pattern suggests a layer structure (i.e., core with its periphery) instead of a complete flat one with equal positions across all the members.
Second, although the interaction patterns of the three projects share some commonalities, their exact shapes are different. The shape of Net-SNMP (as shown in Figure 3) is more like a typical core/periphery compared to the other two. Compiere (as shown in Figure 4) keeps two cores, and the shape looks like a dumbbell. Jboss (as shown in Figure 5), which is the largest project among the three, maintains a more complex structure that shows multiple layers instead of just one core with the rest as peripheries (e.g., Net-SNMP).

Third, as time goes by, the group centralization decreases across the three projects, showing a trend that moves from a centralized structure to a decentralized structure irrespective of project sizes (the three projects with different project sizes are shown in Table 1), project types, and intended audience.

Fourth, the indices of core/periphery fitness of each project fluctuate slightly but maintain a relatively high value (larger than 0.5 on average). However, no observable trend was found across projects.

Fifth, since each project has a relatively large group (i.e., more than 100 actors including all the registered users), the values of density are relatively low with little variation. Therefore, density is not appropriate for comparing the projects.

From the snapshots, we observed the following trend. First, the OSS interaction network evolves into a core/periphery structure. Second, group centralization decreases over time. Third, core/periphery fitness stays relatively stable. To verify our observations, we used longitudinal data generated from the bug tracking systems to analyze the evolution of interaction pattern (discussed in the following section).

**Group Centralization and Core/Periphery Fitness**

Table 3 shows the values of both group centralization and core/periphery fitness over time based on the monthly interaction data. For each figure, the Y-axis indicates the social structure indices (i.e., group centralization or core/periphery fitness), and the X-axis reflects the time dimension.

Two primary observations can be made based on the statistical analysis.

First, the group centralization shows a decreasing trend across the three projects. This observation indicates that as OSS projects progress, the social network structure evolves from centralized to decentralized and then stabilizes. Also, the three figures suggest no substantial differences in the trend among the three projects.

Second, the core/periphery index is maintained at a relatively stable level for each project over time. In addition, the average fitness value stays relatively high for each project (larger than 0.5), indicating a closeness to a perfect core/periphery structure.

Besides a holistic view of network structure for OSS projects, the results also reveal other interesting findings. For example, by examining the core members over time, we found a relatively stable core for each project. The cores are usually project developers and administrators. This observation further demonstrates the existence of strong and stable core as well as loose hangers-on in OSS projects.
DISCUSSION

This research uses the longitudinal data of three OSS projects selected from SourceForge to study the social network structures of OSS teams. The purpose of this study is to investigate the evolution of interaction patterns of OSS project teams. The research results suggest a decrease of group centralization over time and a tendency of core/periphery structure in OSS project teams.

The network plots (as shown in Figures 3-5) indicate a layer structure instead of a flat one as suggested by earlier literature. The interaction pattern evolves from a single hub to a core/periphery structure. As the number of participants increases, a core with only one person (who may be the starter/initiator of the project) cannot satisfy the increasing requirements of development and communication. Therefore, other developers or active users join the core to serve as key members of the project. This results in a more stable structure, and the project is less dependent on a single leader.

With the growth of a software project, more people are attracted to the project. The original leader may not be able to solve all the technical problems encountered in the development process. Each key member has his/her specialty, is responsible for solving relevant problems, and has his/her own periphery in the network plot. Although there are multiple peripheries in the project, collaboration among key members in the project is vital. This phenomenon of distribution and collaboration can be viewed as a critical success factor of OSS development. And the evolvement is vividly demonstrated in our social network analysis.

In a way, the social structure of OSS projects is both centralized and decentralized. On one hand, it is centralized in the sense that there is a core that consists of key members. These key members are responsible for various issues encountered during the development process. On the other hand, it is decentralized in the sense that the decision or communication core is not concentrated on one or two members but a group of key members.

Like any other research, this research has its share of limitations. First, the cases were only selected from SourceForge.net. Although SourceForge is the world’s largest Web site hosting open source software, there are also some other similar Web sites. Therefore, the total number of OSS projects in SourceForge cannot be viewed as the whole population. However, as we argued before, SourceForge is probably the best data collection site for this research.

Second, the bug tracking system was chosen as our data resource. The selection of bug tracking system as our research setting and data resource may have had an effect on the outcome and results. Besides the bug tracking forum, there are other forums that also provide space for participants to communicate with one another, such as mailing lists and feature requests. However, as we highlighted earlier, the bug systems are the most active forum, providing rich interaction data. The bug tracking systems also represent the spirit of open source software development. Examining the interaction data from other forums can be one of our research extensions in the future.

Third, because our research objective is to investigate interaction pattern, we chose projects that have a relatively large number of developers, a large number of bug reports, and relatively long history. Although we tried to involve different types of projects (i.e., different project sizes, project types, and intended audience), these three cases may not be representatives of OSS projects, for example, small projects with only one or two developers and few interactions. Increasing the sample size and including various types of OSS projects is one of our future research directions.
Social Network Structures in Open Source Software Development Teams

IMPLICATIONS AND CONCLUSION

This paper examines the interaction patterns of OSS teams. The research findings suggest that the interaction structure starts from a single hub and evolves to a core/periphery model. We argue that the social structure of OSS teams is both centralized and decentralized. It is centralized in the sense that there exists a relatively stable core that consists of a group of key developers. It is also decentralized because of distributed decision making among key developers and the broad collaboration between developers and users as well as among developers themselves.

The paper presents the evolution of the social structure of OSS projects from a longitudinal perspective. It also provides empirical evidence of the change of interaction patterns from a single hub to a core/periphery model. Moreover, the paper utilizes social network analysis as the research method. This approach has been shown in this research as an effective tool in analyzing the social structure in OSS teams.

Social structure is an important variable for understanding social phenomenon. Open source software, with its open and unique nature, attracts researchers to ask a series of questions. For example, how do participants of OSS projects interact and collaborate with each other? What factors facilitate the interaction and the collaboration? And further, how does the collaboration affect project performance of OSS teams? Social network analysis is a good approach to investigate these questions. This research represents a pioneering effort in this direction.

Chapter 2.18
A Graphical User Interface (GUI) Testing Methodology

Zafar Singhera
ZAF Consulting, USA

Ellis Horowitz
University of Southern California, USA

Abad Shah
R & D Center of Computer Science, Pakistan

ABSTRACT

Software testing in general and graphical user interface (GUI) testing in particular is one of the major challenges in the lifecycle of any software system. GUI testing is inherently more difficult than the traditional and command-line interface testing. Some of the factors that make GUI testing different from the traditional software testing and significantly more difficult are: a large number of objects, different look and feel of objects, many parameters associated with each object, progressive disclosure, complex inputs from multiple sources, and graphical outputs. The existing testing techniques for the creation and management of test suites need to be adapted/enhanced for GUIs, and new testing techniques are desired to make the creation and management of test suites more efficient and effective. In this article, a methodology is proposed to create test suites for a GUI. The proposed methodology organizes the testing activity into various levels. The tests created at a particular level can be reused at higher levels. This methodology extends the notion of modularity and reusability to the testing phase. The organization and management of the created test suites resembles closely to the structure of the GUI under test.

INTRODUCTION

Graphical user interfaces (GUI) are an important part of any end-user software application today and can consume significant design, development, and testing activities. As much as half of the source code of a typical user-interaction intensive application can be related to user inter-
A Graphical User Interface (GUI) Testing Methodology

faces (Harold, Gupta, & Soffa, 1993; Horowitz & Singhera, 1993). GUIs provide an easier way of using various functions of the application by organizing them in a hierarchy of options and presenting only the options which make sense in the current working context. GUIs help users concentrate on the problem instead of putting efforts in remembering all the options provided by the software application that is being used to solve the problem, or searching for the right option from a huge list of options provided by the application. Graphical user interfaces organize the standard user actions and working paradigms into various components that are presented graphically to the user during various usage and application contexts. GUIs enhance the usability of an application significantly. However it also makes application development, testing and maintenance significantly more difficult (Myers, 1993; Wittel & Lewis, 1991). The nature of GUI applications, their asynchronous mode of operation, nontraditional input and output, and hierarchical structure for user interaction make their testing significantly different and difficult from the traditional software testing.

Functional and regression testing of graphical user interfaces is significantly more complex than testing of traditional non-GUI applications because of the additional complexities mentioned in the previous paragraph. A number of commercial tools, like Mercury Interactive’s WinRunner, XRunner and Segue Software’s SilkPerformer, are used in the industry to test graphical user interfaces. These tools provide capture/replay capabilities to test a graphical user interface. Although functionality provided by these tools is sufficient for typical recorded/replay scenarios but they lack an underlying model that can provide more information about the test coverage or to determine the quality of the user interface from a particular functional or implementation perspective. These tools also do not provide a framework that assists in organized and modular testing. The methodology presented in this article uses user interface graphs (UIG) as a framework for organization of test scripts, generation of modular test suites, and coverage analysis of a test execution.

In this article, we propose a methodology for regression testing of graphical user interfaces, with and without a formal specification of the application under test. The remainder of this article is organized as follows: Section 2 highlights some of the best practices and recommendations that help in testing a GUI application in an organized fashion, improve efficiency and effectiveness of testing, reduces possibility of errors, and minimizes repeated work. Section 3 describes the major steps of the proposed methodology. It also introduces a sample X application, called Xman, which is used to demonstrate the effectiveness of the suggested strategy. Section 4 demonstrates the testing methodology when formal specifications of the application under test are not available. Section 5 illustrates the proposed testing methodology when formal specifications of the application under test are available. This section also describes the way statistics are collected during a testing activity and how those can be used to improve the quality of the testing. Section 6 points out the situations when a modification to the application under test might require tuning or recapturing of some of the test scripts. Section 7 concludes the article by summarizing our contribution and providing hints about the future related work.

GUI TESTING: BEST PRACTICES AND RECOMMENDATIONS

In this section, we highlight some of the sought features, well-known best practices and recommendations for planning a testing activity for a graphical user interface.
A Graphical User Interface (GUI) Testing Methodology

- Every element of the GUI should be considered as an object uniquely identifiable by a name. The objects should have a well-defined set of parameters and their response to the outside events should also be well defined.
- The testing activity should be planned carefully around a formal model of the application under test. This model should be powerful enough to provide automatic test generation and coverage analysis.
- Testing of a GUI should be performed in a layered fashion. The list of objects to be tested at a particular level, is either built dynamically while testing at lower levels or from the specifications of the application under test. The list of objects for the lowest level is the basic widget, supported by the underlying toolkit. While testing the highest level, it considers the entire application as a single object. The decision about the number of testing levels and the qualifying criteria for a particular testing level must be made before creating any tests.
- The tests should be organized as a hierarchy of scripts, that is, files containing commands to simulate user actions and verify results. This hierarchy should closely correspond to the object hierarchy of the application under test. Each directory in the hierarchy holds scripts that are related to a particular object and its descendents. The individual scripts should be as small as possible and should test one particular feature of each object. However, if the features are related and simple, then they can be grouped together in the same script.
- Each script should begin with a clean and precise description of the intended purpose of the script and the state of the application required for its proper execution. A script should be divided into three sections. The first section of the script builds the environment required to test the particular feature of the application, the script is intended for. The second section of the script tests the intended feature of the application being tested by the script. The third section restores the state of the AUT and the operating environment, to a point that existed before entering the script.
- A script should be created in such a way that some or all the sections of the script can be executed by calling the script from another script. It provides reusability feature in testing also.
- Instead of manually capturing or replaying the test scripts, a tool should be used to perform these functions automatically and verify the behavior of the application under test. The tool should be capable of addressing an object in the GUI by its symbolic name, instead of its location, dimensions or any other contextual information.
- The data for the result verification should be captured in terms of object attributes when possible and only those attributes should be captured which are critical to verify the functions of the application, being tested by the current script. If image comparisons are unavoidable, then the images should be captured with reference to the smallest enclosing object and area of the captured images should not be more than absolutely required. The number of verifications should also be kept to an absolute minimum especially when image comparisons are involved.
- The script commands to simulate user actions during the replay and the data for verification of the AUT behavior should be kept separately. This separation is required because the verification data might change depending on the environment while the script commands should be independent of the environment and should be valid across multiple platforms. If script commands and verification data are stored separately, then it is easier to port a test suite across multiple platforms. In fact, a good tool should
automatically perform the porting from one hardware platform to the other.

Proposed Methodology for GUI Testing

This section proposes a methodology for the testing of a graphical user interface (GUI). This proposed methodology is suitable particularly when one has a tool similar to Xtester (Horowitz & Singhera, 1993). It follows the recommendations provided in the previous section. The methodology works in the following two scenarios:

i. Testing without formal specifications/model of the application under test
ii. Testing with a formal model of the application.

Both these scenarios are described in the following subsections.

Testing without a Formal Model

Creation of formal specifications of a GUI application for its testing purposes is a difficult task and requires a significant amount of effort. It is also not feasible to invest resources in creating the formal specifications of the application; hence the testing has to be performed without it. The best thing that can be done in such a situation is to incrementally build a test hierarchy for the application, by capturing-user sessions in an organized way. Automatic test generation or coverage analysis is not possible without formal specifications of the application under test. The major steps of the proposed methodology to test an application without a specification are given below:

Step 1: Initialization

Make basic decisions about the testing activity. Some of the most important decisions, which must be taken at this point, are:

Display the object on the screen and verify its appearance;
If the object has sub-objects
   Add its immediate sub-objects at the top of the list;
If the object qualifies for a higher testing level
   Add it to the list of objects for the higher level;
Send expected events to the object and verify its response;
If a new object appears in response to the event
   if the new object is not listed as a tested object
      Add it to the end of the list;
      Pop down the object from the screen;
Mark the object in the list as tested;
• The number of testing levels and criteria to build list of objects for a particular level.
• Initialize a list of objects for each level that holds the names and some information about the objects of the user interface. The information includes the way the object can be mapped on the screen, the mechanism to unmap it from the screen, and if it has been tested or not.
• The location of the test suite and its organization.
• The application resources that will be used during this testing activity should be listed.

Step 2: Building the Initial Object List

Go through the documentation of the application under test and find all the top-level windows, which might appear as starting windows of the application. These windows and their related information is added to the list of objects for the first testing level and marked as tested.

Step 3: Building Test Suite

Take the first object from the top of the object list, which has not been tested, and create test scripts for it. The procedure for creating test scripts for a particular object is given in Figure 1. The sub-objects of the object under test are added to the list of objects by scanning the object from left to right and top to bottom. Keep on taking objects from the top of the object list and testing them until all the objects in the list are marked as tested. When the list associated with a particular level has no untested object, start testing objects from the list, associated with the next higher level. This process continues until all the levels are tested.

Step 4: Creating Script Drivers

Write higher level scripts for all the top level windows for any other complex objects, each of the testing levels and for the entire test suite. These scripts will replay all the scripts related to the object and its descendents. The highest-level script driver should replay each and every script in the suite.

Step 5: Testing the Test Suite

Make sure that all the scripts and script drivers work properly and cover all the features of the application, which needs to be tested. One cannot do much automatically to determine the quality of a test suite, in the absence of a formal model of the application under test. After the creation of the test suite, run the highest-level script driver to verify that all the scripts in the suite are capable of properly replaying and trying to match the features covered by the test suite with those included in the test requirements or application documentation.

Testing with a Formal Model

The strategy to build test scripts without a formal specification, discussed in the previous subsection, puts a lot of responsibility on the person creating those scripts. The strategy also requires that the application under test should be running reliably before the capturing of script is even started. The scripts created without any formal specification are also vulnerable to any modification in the application, which affects its window hierarchy. It requires that after making any changes to the application under test, the affected scripts should be located manually and recaptured or tuned to offset the modification in the application. It is also not possible to create test scripts automatically or to get a coverage measure after running a set of test suites. To overcome these drawbacks and get access to advanced features like automatic test generation and coverage analysis, one has to invest
some effort to formally specify the application under test. This section provides a methodology to test an application when its formal specification is provided or resources are available to build such a specification. The following are the major steps of the testing methodology when a formal specification of an application under test is available.

**Step 1: Building the Model**

Build a user interface graph of an application under test. When resources permit, the very first step in testing the application should be to build a formal model of the application under test. XTester provides such a formal model, called user interface graph (UIG). UIG provides information about the object hierarchy of the application. It also provides information about the nature of a particular object and the effects of an event in an object to the other objects in the user interface. A UIG can be built manually by creating a user interface description language (UIDL) file, or it can be created semi-automatically by steering through the application under test and filling in the missing information about the objects (see Horowitz & Singhera, 1993) for more details on syntax of UIDL and UIG).

**Step 2: Initialization**

Make basic decisions about the testing activity. Some of the most important decisions, which must be taken at this point, are listed as follows:

- The number of testing levels and qualifying criteria for each testing level.
- The location of the test suite and its organization.
- The application resources that will be used during this testing activity.

**Step 3: Build Object Lists**

Build a list of objects for each testing level. After building the formal model, it is possible to build the object lists for all testing levels. The procedure for building those lists is to start from the root of the UIG and perform a post-order walk of the object hierarchy. Add each visited node to the object lists associated with the levels, for which it qualifies.

**Step 4: Building Test Suite**

The strategy for capturing scripts without any formal specification, which has been discussed in the previous section, can also be used for capturing scripts when the application has been specified formally. However, capturing scripts with formal specifications provides us some additional advantages over the scripts which have been captured without any specification. These advantages include an overall picture of the application under test, and hence a more efficient test suite, a test suite which is less affected by the changes in the application, automatic test generation, and coverage analysis.

**Step 5: Creating Script Drivers**

Write higher level scripts for all the top level windows or any other complex objects, each of the testing levels and for the entire test suite. These scripts will replay all the scripts related to the object and its descendents. A highest-level script driver should replay each and every script in the suite. These scripts can also be created automatically.

**Step 6: Coverage Analysis**

Once a test suite has been created; it should be replayed in its entirety to determine the coverage provided by the test suite. This coverage should
be performed at each level, that is, the coverage criteria for level-I should be the verification of all the objects in the application that have been created, mapped, unmapped and destroyed, at least once and every event expected by an object, has been exercised on it at least once. The criteria for higher levels is to make sure that all the interactions and side effects among objects which make a composite object at the corresponding level, has been verified.

**AN INTRODUCTION TO XMAN**

In this section, we introduce the application Xman, which is used to demonstrate the effectiveness of the methodology, discussed in the previous section. Xman is a small application which is distributed with the standard $X$ release. It provides a graphical user interface to the UNIX *man* utility. It has been developed using the Athena widget set and some of its windows are shown in Figure 1. The following paragraphs briefly describe the functionality of Xman.

When Xman is started, it displays its main window, called Xman, by default. This main window contains three buttons: Help, Manual Page and Quit. Clicking on the manual page button, it displays a window, called manual page. A Help window is displayed when the help button is clicked. The quit button is used to exit from Xman.

The manual page window is organized into various sections. A breathe top of the window contains two menu buttons, options and sections, in the left half and a message area in the right. The rest of the area below the bar, called text area, is used to display the names of the available manual pages in the currently selected section, and the contents of the currently selected manual page. Both the names and contents portions of the text area are resizable and have vertical scrollbars on the left.

The Options menu contains the following entries:

- **Display Directory**: It displays names of manual pages in the entire text area.
- **Display Manual Page**: It displays contents of the currently selected manual page in the entire text area.
- **Help**: It displays a help window.
- **Search**: It displays a dialog box to enter the name of a manual page to search for.
- To show both screens, the area is vertically divided into two halves, with the upper half showing the directory contents of currently selected man page section and the lower half showing the contents of the currently selected manual page. This option toggles to Show One Screen and also disables menu entries Display Directory and Display Manual Page.
- **Remove This Manpage**: It removes the Manual Page window from the screen.
- **Open New Manpage**: It creates another Manual Page window.
- **Show Version**: It displays the current version of Xman in the Message area
- **Quit**: exits from the Xman application.

The Sections menu contains one option for each manual page section available on the system. The standard options are User Commands, System Calls, Subroutines, Devices, File Format, Games, Miscellaneous, and System Administration.

The Help window displays a limited version of the Manual Page window. The window has exactly the same structure as the Manual Page window but the Sections menu button and the first five options in the Options menu are disabled. It displays man page for Xman itself. No more than one Help window can exist at a time while an arbitrary number of Manual Page windows can be created.

The testing of Xman has been organized in three layers. The first layer verifies the behavior of
individual GUI objects. The second layer verifies the inter-object effects among objects belonging to the same top level window. The third layer verifies the inter-object effects among objects belonging to different top level windows. The following sections provide details of this testing activity.

TESTING WITHOUT FORMAL SPECIFICATIONS

This section provides a demonstration for the testing of Xman, when no formal model is available for it. The following subsections demonstrate each step of the methodology, described in Section 2.

Initialization

• **Number of testing levels:** As Xman is a fairly small and simple application, so the testing activity is organized in three (3) levels. The first level tests the individual objects in Xman. The second and third levels verify the interactions and side effects of the objects which belong to the same top level window and different top level windows, respectively.

![Figure 2. Main windows of Xman](image-url)
Figure 3: Test Suite Hierarchy of Xman
• **Location of the test suite:** Suppose that the root directory for the test suite being captured, is Xman Test. This directory contains resource file(s) used during testing, and the result files are created in the directory, by default. It also has three subdirectories, that is, Level-1, Level-2 and Level-3, one for each testing level.

• **Object list:** A list of objects, called *Obj List*, is initialized. This list contains information about the objects and is initialized to be empty.

• **Application resources:** ~/XmanTest/Xman.Defaults is the file which contains the default application resources of Xman for this testing activity and these resources always remain the same.

**Building the Initial Object List**

By default, Xman starts with a top box, called Main Window in Figure 2. However, a command line option, -notopbox, is available which can be used to bypass the Main Window and display the Manual Page window directly. As Main Window and Manual Page window are the only windows, which can appear when Xman is started, so the initial object list contains only these two objects.

**Building the Test Suite**

This section provides the details on building all the three testing levels for Xman. To make things simple, we only discuss the creation of test suites related to the Main Window of Xman. We ignore any keyboard accelerators to which Xman responds. The test suites for other windows can be created in a similar way. Figure 3 provides the hierarchy of scripts related to the Main Window for all the three testing levels.

**First Level**

Suppose that the initial object list is built in such a way so that Xman Main Window is on the top of the list. We select it as the object under test and create a new directory, called ~/XmanTest/Level-1/Xman to build test scripts related to the first level testing. The scripts related to Xman Main window object display itself the window on the screen, exercise all the window manager operations on it, and then finally pop-down the window. DspXmanWin.scr script pop-up the Xman window and verifies that looks right. RemoveXmanWin.scr script in its entering section to display the Xman window. It verifies the window manager operations in its core section and then uses RemoveHelpWin.scr script in its leaving section to pop-down the Xman Window. As soon as the Xman window pops up on the screen, we see that it contains four objects, i.e., Manual Browser Label, Help, Quit and Manual Page. There are buttons which are Quit and Manual Page. Manual Browser label is a static piece of text and does not respond to any user actions, so we do not need a script for it. The other three (3) objects are active objects and respond to user events so we create one script for each of them. The entering section of each one of these scripts calls DspXmanWin.scr to display the Xman Main Window on the screen. The ending section of each of these scripts call RemoveXmanwin.scr to remove the Xman Main Window from the screen. The core section of Help Button.scr script verifies the behavior of Help button in Xman Main Window when it is clicked on by a mouse button. The core sections of QuitButton.scr and ManPageButton.scr scripts verify the same thing for Quit and Manual Page buttons in Xman Main Window.
Second Level

The object list of the second level contains all the top level windows of Xman. As we are considering the **Main Window** only in this discussion so we assume that it is at the top of the list and is selected for the testing. There is not much interaction going on in the objects which belong to the Xman **Main Window**. The only interaction is the disappearance of **Main Window**, in response to click on the Quit button. So there will be only one script related to the Main Window which will verify that a click on the Quit button actually destroys the Main Window of Xman. This script is called **MainWindow.scr** and is located in ~*/XmanTest/Level2/*/. This script is also used DspXmanWin.scr and RemoveXman.scr script to display and remove the Main Window from the screen. Another potential script, let us call it XmanOrder.scr, related to the Main Window verifies that the order in which Help or Manual Page buttons are pressed is insignificant. No matter the Help button is pressed before or after the Manual Page button, it displays the Help window properly. The same is also true for the Manual Page button.

Third Level

The object list of the third level includes the root object only, and tests any interactions among the top level windows of Xman can be done. Such interactions which involve the Main Window of Xman include display of the Help window and the Manual Page window in response to mouse clicks on the Help and the Manual page buttons, respectively. Similarly, it also includes disappearance of all the windows related to Xman in response to a click on the Quit button. The three scripts provided at this level, that is, Help.scr, ManualPage.scr and Quit.scr, verify the behavior, related to the corresponding button, mentioned above. This level might also include scripts which verify application behavior, like multiple clicks on the Help button and do not create more than one Help windows while each click on the Manual Page button create a new Manual Page window.

Creating Script Drivers

Once all the scripts for Xman has been captured, we need driver scripts so that all the scripts in the entire suite, all the scripts in a particular testing level or all the scripts related to a particular object can be executed automatically in the desired sequence. For example, we create a script driver, at each testing level, which executes all the scripts created for testing Xman Main Window and its descendents, at that particular level. These scripts are ~*/XmanTest/Level-1/Xman/All.scr, ~*/XmanTest/Level-2/Xman/All.scr, and ~*/XmanTest/Level-3/Xman/All.scr, respectively. The script ~*/XmanTest/Level-1/All.scr drive all the scripts created for the first testing level and similarly the other two drivers execute scripts related to the other two levels. The script ~*/Xman-Test/All.scr drives all the scripts in all the three levels of the test suite.

Testing the Test Suite

After the creation of the test suite, it is necessary to replay all the scripts in the suite and verify if they work properly and also to make sure that they cover all the features which need to be tested. Although, without a formal specification, it is impossible to perform any reasonable automatic coverage analysis but at least the replayed events and the objects which appear during the replay, can be matched against application documentation to determine if any object or event has not been covered by the generated test suite.

TESTING WITH FORMAL SPECIFICATIONS

This section demonstrates the testing of Xman when we have enough resources to build a formal
model for Xman. The following subsection illustrates each step of the methodology, described in Section 2.2.

**Building the Model**

When the resources permit, the first step for testing is building a formal model for the application under test. Figure 4 displays a User Interface Graph built for Xman. The Root node of the graph represents the root window of the screen. The children of the Root node represent the six top level windows of Xman. The nodes at lower levels in the graph represent the descendants of the top level windows. Let us take the main window of Xman as an example. It is represented as MainWin node in the User Interface Graph. The child of the MainWin node is the Form node which acts as a container widget for the buttons and the label in the main window. The ManPage, Quit and Help nodes represent the Manual. Page, Quit and Help command buttons in the main window, respectively. The label node represents the Manual Browser label in the main window. The dark black arc from the ManPage node to the Manual Page node represents the fact that clicking a mouse button over the ManPage button in the main window affects the top level window, called Manual Page. The arc from the Quit node to the Root node represents that a click on the Quit button affects all the top level windows of Xman. The type of event represented by an arc is reflected by the drawing pattern of the arc. The
two arcs mentioned above have the same pattern and represent button clicks. An arc with a different pattern is the arc from the Text node to the search node. This pattern represents text entry and the arc represents that entering text in the Text node affect the search dialog box.

**Initialization**

All the decision and actions taken at the initialization step, that is, the number of testing levels and their organization, the location of the test suite and the application default resources, is kept the same as for testing without a formal specification, described in Section 4.1.

**Building Object Lists**

After building the user interface graph for Xman, it is possible to build object lists for all levels of testing. This can be done either manually or automatically by scanning each and every node in the User Interface Graph and verifying if it qualifies to be tested on a particular testing level. All the objects in Xman qualify for the first testing level and hence are placed on the list associated with it. The qualifying criterion for the second level is that the object must be a top level window, that is, its corresponding node must be a child of the root of the user interface graph. Some of the objects which qualify for the second testing level are Xman Main Window, Manual Page window, Help window, Search dialog box and so forth. The third level treats the entire Xman application as a single object, and its corresponding node, the root, is the only object which qualifies for the third level of testing.

**Building Test Suite**

The strategy for capturing scripts without any formal specifications, discussed in Section 4.3, can be used for capturing scripts when the application has been specified formally. However, capturing scripts with formal specifications also provides us the capability to write the test scripts manually or generate test scripts automatically by using the formal model and the test requirements. All of these three techniques for building a test suite are explained in the following section.

**Capturing Scripts**

A tool can be used for capturing user sessions for building a test suite, in exactly the same way as for capturing without a formal model, as mentioned in Section 4.3. However, the presence of a formal model makes the generated scripts more robust and easy to follow and debug. A formal model also provides the flexibility that the captured scripts can be executed in any order without any conflict in window names. It becomes easier to modify the test suite in case of a modification to the application under test. In fact in most cases the modification can be reflected in the specification file and the test suite remains valid without making any changes.

**Writing Scripts Manually**

The formal specifications of the application, under test, also allows the user to write scripts manually, even for the first level of testing. This feature is particularly helpful when the test scripts need to be created in parallel with the application development in order to reduce the total development time. The way it can be organized is to formally specify the graphical user interface of the application once the design is complete. The developers and testers agree on this formal specification and any future changes are properly communicated between the two groups. Having the formal specification of the graphical user interface at hand, the testers can develop the scripts manually in parallel with the application development. Once the object hierarchy and the behavior of the objects is known, the manual writing of test scripts is as easy as writing a UNIX shell script.
Automatic Test Generation

The formal specifications of an application under test also provide capabilities to generate test scripts automatically. A tool can be developed, which will read the specifications of an application and create test scripts for a particular level of testing or the entire test suite. Similar tools can be developed and used to generate test scripts to test all the objects of a particular type or all the user actions of a particular type. For example, such a tool can generate test scripts to exercise clicks on each command button in an entire application. A similar tool can generate a suite of test scripts to verify that all windows in an application under test are displayed on the screen at least once. Another tool might generate scripts to individually select all the options of each menu in the application and verify that the application responds in the expected manner. There can be another tool that will create scripts for the selection of multiple menu options and/or command buttons in different sequences to verify the application response. All the mentioned tools will only create scripts and validation data that have to be captured by replaying these scripts and by using caprep (Horowitz & Singhera, 1993) or a similar tool to replay these scripts in Update mode.

The logic behind these automatic test generation tools is the same as it is used in Section 5

Figure 5. Pseudo Code for Automatic Test Generator

```
Build the User Interface Graph of the application under test;
Build an object list by a pre-order traversal of the User Interface Graph using parent-child relationship arcs.
for each "element on the list"
  do
    if the element is a top level window
      Create a new directory and change to the directory.
      Display the element on the screen.
    fi
    if the element accepts any user events
      Create a script for the element
      for each kind of user event accepted by the element
        do
          Add commands in script to
          Generate the event on the element;
          Verify the effect of that event;
          Undo the effect of the event;
        done
    fi
  done
```
A Graphical User Interface (GUI) Testing Methodology

for manual creation of test suites. The tool starts at the root of the UIG and builds a list of GUI elements by performing a pre-order walk of the UIG. During this walk only the arcs that represent parent-child relationships are considered. After building this list, its entries are taken one by one to create test scripts for them. If the current GUI element, taken from the list, is a top-level window, then a separate directory is created for it and the scripts for the element and all of its

</table>
descendents are created in that directory. If the currently selected element belongs to the category for which a script is required, then following the arcs that represent user actions on the element creates one. Figure 4 shows the pseudo code for such an automatic test generator.

Coverage Analysis

No testing activity is useful unless it provides some coverage measures/analysis. This coverage measure reflects the quality of the testing activity. The UIG provides us with a framework to determine such a coverage. During capture or replay of scripts, XTester keeps track of the user actions and their effects on individual objects. This information is available in a .stt file at the end of the testing activity. Currently, the information captured in .stt about a particular object includes the number of times it was created, mapped, unmapped, and destroyed. It also accumulates the number of times a mouse button or keyboard key was pressed or released over the object. This information helps the user to locate any particular objects in the application which have not been created, destroyed, mapped, unmapped, or received a user event. These statistics can also be used for improving the efficiency of the test suite by removing the repetitive testing of the same characteristics, whenever possible. Figure 6 shows a file created by XTester after replaying a certain test suite for Xman. The legend is displayed at the top of the file to describe acronyms for various actions. The next line after the legend provides the heading for the table. Each line in the table provides statistics about a particular object. For example, the very first line of the table provides statistics about the Main Window of Xman, named Xman. This particular line shows that the object named Xman was created once, never destroyed, mapped twice on the screen and unmapped once, by the corresponding test script. It also shows that the corresponding test suite never exercised a button press/release or key press/release events on the Xman object.

Tools can be developed to extract information from a .stt file. Analysis tools are developed that take a .uidl file to build a UIG of the application under test, and a .stt file to get statistics collected from a particular test run. The tool maps the collected statistics on to the object hierarchy and produces an annotated graph. Queries can be run on this annotated graph to determine the effectiveness of the test suite. For example, one can see how

Figure 7. Pseudo code for quality analyzer

| Display the required information in proper format; |
| done |

---

A Graphical User Interface (GUI) Testing Methodology
many nodes and arcs in the object hierarchy have not been exercised by this particular test suite, or see the objects and inter-object arcs to determine objects that did not receive an expected user action. Similarly, one can filter out the objects that did not receive an expected user event to create an annotated graph that satisfies a particular criterion.

INVALIDATION OF TEST DATA

XTester captures information as two entities, script commands and verification data and saves them in different files, .scr and .img, respectively. This section describes the scenario in which created test script(s) might fail and has to be re-captured or re-written. The following scenarios invalidate some of the captured scripts:

- An application is modified in such a way that WM_NAME property of a top-level window is changed. This modification will only affect the scripts that have been captured without a specification and are related to the window whose WM_NAME property was changed. The scripts captured with a formal specification remain unaffected, provided the relevant specifications are also modified to reflect the change in the application.

- The application is changed so that the order or number of children of a particular node is changed. The scripts that are captured without a specification and address objects in the modified hierarchy, are affected and have to be recaptured or tuned. However, the scripts captured with a formal specification remain unaffected provided the specification is also modified accordingly. XTester provides option to build either full or short object names. If the application is modified so that the depth of a hierarchy is changed, then all the fully qualified names belonging to that hierarchy will no longer be valid names and has to be modified to reflect the change. However, short names that are relative to their immediate parents will still remain valid.

- If object information has been captured as an image, then trying to replay the scripts on another workstation that is incompatible with the workstation on which image was captured will give false alarms. The scripts work fine across multiple platforms, however, verification data is the platform specific in case of images. An easier way of creating verification data for a new hardware platform will be to replay all the scripts in Update mode that replaces the current verification data with the newly available one.

CONCLUSION AND FUTURE DIRECTIONS

In this article, we have suggested guidelines that are useful in planning a testing activity for a graphical user interface (GUI). We have also presented a methodology for testing a GUI, both when specifications of an application under test is not available, and when such specifications are provided or resource code is available to build such a specification. This article also demonstrates the use of the proposed methodology to test a sample X application, Xman, with or without specifications. It also illustrates how the model is helpful in automatic test generation and coverage analysis. In the end, we describe the situations in which the scripts captured by XTester become invalid.

The methodology and the underlying UIG framework discussed in this article can be very effectively used to model and test web sites and web applications. We are actively working to extend this proposed methodology to be used for testing web-based applications and semantic web applications.

Chapter 2.19
Socio–Cognitive Engineering

Mike Sharples
University of Nottingham, Jubilee Campus, UK

INTRODUCTION

Socio-cognitive engineering is a framework for the systematic design of socio-technical systems (people and their interaction with technology), based on the study and analysis of how people think, learn, perceive, work, and interact. The framework has been applied to the design of a broad range of human-centered technologies, including a Writer’s Assistant (Sharples, Goodlet, & Pemberton, 1992), a training system for neuroradiologists (Sharples et al., 2000), and a mobile learning device for children (Sharples, Corlett, & Westmacott, 2002). It has been adopted by the European MOBIlearn project (www.mobilearn.org) to develop mobile technology for learning. It also has been taught to undergraduate and postgraduate students to guide their interactive systems projects. An overview of the framework can be found in Sharples et al. (2002).

BACKGROUND

The approach of socio-cognitive engineering is similar to user-centered design (Norman & Draper, 1986) in that it builds on studies of potential users of the technology and involves them in the design process. But users are not always reliable informants. They may idealize their methods, describing ways in which they would like to or have been told to work, rather than their actual practices. Although users may be able to describe their own styles and strategies of working, they may not be aware of how other people can perform a task differently and possibly more effectively. Surveys of user preferences can result in new technology that is simply an accumulation of features rather than an integrated system.

Thus, socio-cognitive engineering is critical for the reliability for user reports. It extends beyond individual users to form a composite picture of the human knowledge and activity, including cognitive processes and social interactions, styles and strategies of working, and language and patterns of communication. The term actor is used rather than user to indicate that the design may involve people who are stakeholders in the new technology but are not direct users of it.

The framework extends previous work in soft systems (Checkland & Scholes, 1990), socio-technical and cooperative design (Greenbaum & Kyng, 1991; Mumford, 1995; Sachs, 1995), and the application of ethnography to system design.
Socio-Cognitive Engineering

(see Rogers & Bellotti [1997] for a review). It incorporates existing methods of knowledge engineering, task analysis, and object-oriented design, but integrates them into a coherent methodology that places equal emphasis on software, task, knowledge, and organizational engineering.

The framework also clearly distinguishes studying everyday activities using existing technology from studying how the activity changes with proposed technology. It emphasizes the dialectic between people and artefacts; using artefacts changes people’s activities, which, in turn, leads to new needs and opportunities for design.

FRAMEWORK

Figure 1 gives a picture of the flow and main products of the design process. It is in two main parts: a phase of activity analysis to interpret how people work and interact with their current tools and technologies, and a phase of systems design to build and implement new interactive technology. The bridge between the two is the relationship between the Task Model and the Design Concept. Each phase comprises stages of analysis and design that are implemented through specific methods. The framework does not prescribe which methods to use; the choice depends on the type and scale of the project.

It is important to note that the process is not a simple sequence but involves a dialogue between the stages. Earlier decisions and outcomes may need to be revised in order to take account of later findings. When the system is deployed, it will enable and support new activities, requiring another cycle of analysis, revision of the Task Model, and further opportunities for design.

The elements of socio-cognitive engineering are as follows:

- **Project**: The diagram shows the process of design, implementation, and deployment for a single project.
- **Actors**: Different types of people may be involved in or affected by the design and deployment, including (depending on the scale of the project) design, marketing and technical support teams, direct users of the system, and other people affected by it (e.g., administrative staff).
